(Received 28 June 2016; published 16 September 2016)

The critical current of a Josephson junction is an oscillatory function of the enclosed magnetic flux $\Phi$, because of quantum interference modulated with periodicity $\hbar/2e$. We calculate these Fraunhofer oscillations in a two-dimensional (2D) ballistic superconductor–normal-metal–superconductor (SNS) junction. For a Fermi circle the amplitude of the oscillations decays as $1/\Phi$ or faster. If the Fermi circle is strongly warped, as it is on a square lattice near the band center, we find that the amplitude decays slower, $\propto 1/\sqrt{\Phi}$, when the magnetic length $l_m = \sqrt{\hbar/2eB}$ drops below the separation $L$ of the NS interfaces. The crossover to the slow decay of the critical current is accompanied by the appearance of a 2D array of current vortices and antivortices in the normal region, which form a bipartite rectangular lattice with lattice constant $\sim l_m^2/L$. The 2D lattice vanishes for a circular Fermi surface, when only the usual single row of Josephson vortices remains.

1. INTRODUCTION

A junction between two superconductors responds to an imposed magnetic flux $\Phi$ by producing a chain of circulating current vortices, known as Josephson vortices [1]. The critical current $I_c(\Phi)$ oscillates with period $\Phi_0 = h/2e$ and amplitude $\propto \Phi_0/\Phi$. These so-called Fraunhofer oscillations are a macroscopic quantum interference effect, first observed in 1963 in a tunnel junction [2]. The effect is now used as a sensitive probe of ballistic transport and edge currents in graphene and topological insulators [3–8].

Since the self-field of the current vortices is typically too weak to screen the imposed magnetic field $B$ from the junction area, the arrangement of Josephson vortices is governed by quantum interference—unaffected by the classical electrostatics that governs the two-dimensional (2D) Abrikosov vortex lattice in the bulk superconductor [1]. The fundamental question addressed here is whether quantum interference by itself is capable of producing a 2D vortex lattice in a Josephson junction. It is known that the linear arrangement of the vortices along the superconducting interface is modified by insulating boundaries [9–12], in a junction of lateral width $W$ comparable to the separation $L$ of the interfaces. But in wide junctions ($W \gg L$), when boundary effects are irrelevant, only linear arrangements of Josephson vortices are known [13–17].

We have discovered that a 2D Josephson vortex lattice appears when the circular Fermi surface acquires a square or hexagonal distortion. Such a warped Fermi surface has flattened facets that produce a nonisotropic velocity distribution of the conduction electrons, peaked at velocity directions normal to the facets. Analytical and numerical calculations of the supercurrent distribution in the high-field regime (magnetic length $l_m = \sqrt{\hbar/2eB}$ less than $L$) reveal the appearance of multiple rows of current vortex-antivortex pairs, forming a 2D bipartite rectangular lattice in the normal region with lattice constant

$$a_{vortex} = \frac{W\Phi_0}{\Phi} = \frac{\pi l_m^2}{L}. \tag{1.1}$$

As shown in Fig. 1 (resulting from a numerical simulation discussed in Sec. VII), in the weak-field regime $l_m \gtrsim L$ there is only a single row of $W/a_{vortex}$ vortex-antivortex pairs. However, when $l_m$ drops well below $L$ multiple rows of vortex-antivortex pairs appear. The appearance of this 2D current vortex lattice is associated with a crossover from a $1/B$ to a $1/\sqrt{B}$ decay of the amplitude of the Fraunhofer oscillations. In contrast, for a circular Fermi surface the oscillations in a ballistic SNS junction with a warped Fermi surface

FIG. 1. Supercurrent density in an SNS (superconductor–normal-metal–superconductor) Josephson junction, resulting from the numerical simulation of Sec. VII on a square lattice with a half-filled band and a square Fermi surface (lattice constant $a_0$, normal region of size $W = 10L = 300a_0$, band width $2E_0$, Fermi velocity $v_F \equiv E_0 a_0/\sqrt{2}\hbar$, resulting in $N = 282$ transverse modes per spin direction at the Fermi level, superconducting gap $\Delta = 2.5 \times 10^{-3} E_0 \gg \xi \equiv \hbar v_F/\Delta = 283a_0$, zero phase difference). The two panels are for a weak and a strong perpendicular magnetic field, both at a low temperature $k_B T / \Delta = 10^{-2}$ in the short-junction regime $L/\xi = 0.1$. The cyclotron radius $l_{cycl}$ remains large compared to $L$ also for the strongest fields considered, $l_{cycl} = (W/a_0)(\Phi_0/\Phi) \gtrsim 10$. A bipartite square lattice of vortex-antivortex pairs in the normal region (lattice constant $a_{vortex} = \pi l_m^2/L$) forms in the lower panel. Notice the edge reconstruction of the current vortex lattice, producing an edge channel of width $\sim l_m$ large compared to $a_{vortex}$. This edge channel results purely from magnetic interference; it is unrelated to the skipping orbits along the edge that would form in higher fields (when $l_{cycl} < L$).
amplitude crosses over to an accelerated $1/B^2$ decay when $l_m < L$ [18].

The outline of this paper is as follows. In Secs. II and III we formulate the problem of magnetic interference in a ballistic Josephson junction and present the semiclassical analytical solution for the current distribution. The resulting current vortex lattice is described in Sec. IV, far from the lateral boundaries. As shown in Sec. V, within a magnetic length $l_m$ from the boundaries there is a lattice reconstruction that produces an edge channel purely as a result of quantum interference, at magnetic fields that are still so weak that the curvature of the trajectories due to the Lorentz force can be neglected. Because of the edge channel the amplitude crosses over to an accelerated $1/B^2$ decay when $l_m < L$ [18].

A perpendicular magnetic field $B$ (magnetic length $l_m = \sqrt{\hbar/eB}$) produces oscillations in the critical current of the Josephson junction (Fraunhofer oscillations), periodic with period $\Phi_0 = \hbar/2e$ in the enclosed flux $\Phi = BWL$. We assume that the magnetic field is screened from the S region by a short screening length in the bulk superconductors, even in the high-field regime $l_m \ll L$.

In the analytical calculation we take the semiclassical limit $k_F L \gg 1$, in which bound states in the junction can be associated with classical trajectories. The junction is ballistic (no impurity scattering), so the trajectories are arcs of cyclotron radius $l_{cycl} = h k_F/eB$. We assume that $k_F L$ is sufficiently large that the ratio $l_{cycl}/L = k_F L \times (l_m/\xi_1)^2$ remains $\gg 1$ for the largest fields considered, so we neglect the curvature of the trajectories in the analytical calculation (but not in the numerics). In particular, skipping orbits along the edge play no role in our analysis.

The single-electron dispersion relation $E_k$ has a nonisotropic dependence on the 2D wave vector $k = (k_x, k_y)$, resulting in a nonisotropic distribution of the velocity $v_k = h^{-1} \partial E_k/\partial k$ over the Fermi surface. Our analysis is general, but for a specific example we consider the warping of the Fermi surface on a square lattice (unit lattice constant), with dispersion relation

$$E_k = E_0 - \frac{1}{2} E_0 (\cos k_x + \cos k_y)$$

$$\Rightarrow v_k = \frac{E_0}{2\hbar} (\sin k_x, \sin k_y).$$

The Fermi surface is deformed from a circle to a square as we raise the Fermi energy from the bottom of the band to the band center. For later use we record the relation at the Fermi energy $E_F = E_0$ between $k_x$ and the angle of incidence $\theta$ on the NS interface:

$$\tan \theta = \frac{v_x}{v_y} = \frac{\sin k_x}{\sqrt{1 - (\cos k_x + 2E_F/E_0 - 2)^2}},$$

$$-k_F < k_x < k_F, \quad k_F = \arccos (1 - 2E_F/E_0).$$

### III. SEMICLASSICAL CALCULATION OF THE SUPERCURRENT

In the semiclassical (WKB) approximation [19] a bound state at energy $|\epsilon| < \Delta$ corresponds to a periodic classical trajectory that traverses the junction, accumulating a phase shift that is a multiple of $2\pi$. We distinguish two types of periodic trajectories: one in which an electron propagates from superconductor $S_1$ to $S_2$, is Andreev reflected as a hole and retraces its path to $S_1$, and another in which a hole propagates from $S_1$ to $S_2$ and retraces its path as an electron. The first path is indicated by $\sigma_{eb} = +1$, the second path by $\sigma_{eh} = -1$.

For a given periodic trajectory the total phase shift is given by

$$\phi_{total} = -2 \arccos (\epsilon/\Delta) + \sigma_{eh} (\phi - \gamma).$$

$$\gamma = \frac{2e}{\hbar} \int_{S_1} A \cdot dl.$$
The $\epsilon$-dependent term, which has the same sign for $\sigma_{cb}=\pm 1$, is the phase shift accumulated over a penetration depth in the superconductor (in the Andreev approximation $\Delta \ll E_F$). The $\sigma_{cb}$-dependent terms consist of the contribution from the pair potential in $S_1,S_2$ (phase difference $\phi = \phi_1 - \phi_2$) and the phase shift $\gamma$ accumulated in the $N$ region from the vector potential $A = (0,Bx,0)$.

In the short-junction regime $L \ll \xi$ we may neglect the phase shift in $N$ arising from the energy difference $2\epsilon$ of electron and hole $[21]$. For $0 < \phi - \gamma < \pi$ the spin degenerate bound state corresponding to this periodic trajectory is at energy $\sigma_{cb}\epsilon$ with

$$\epsilon = \Delta \cos(\phi/2 - \gamma/2). \quad (3.2)$$

A tube of width of the order of the Fermi wavelength, extending along the trajectory that passes through the point $(x_0,y_0)$ at an angle $\theta$ with the $y$ axis, can be thought of as a single-mode waveguide connecting the two superconductors. In thermal equilibrium at temperature $T$ the single-mode supercurrent is given by $[22]$

$$\delta I(x_0,y_0,\theta) = -\tan \left( \epsilon \frac{2e}{2k_B T} \right) \frac{2e}{\hbar} \frac{d\epsilon}{d\phi}$$

$$= \frac{e\Delta}{\hbar} \sin(\phi/2 - \gamma/2) \times \tanh \left( \frac{\Delta \cos(\phi/2 - \gamma/2)}{2k_B T} \right), \quad (3.3)$$

including a factor of 2 from the spin degeneracy. The trajectory dependence enters via the phase shift $\gamma \equiv \gamma(x_0,y_0,\theta)$. Notice that, notwithstanding the appearance of the half-phases $\phi/2$, the supercurrent is $2\pi$ periodic in $\phi$, as it should be.

The total supercurrent $I$ through the Josephson junction follows upon integration of Eq. (3.3) over the phase space of the propagating modes at the Fermi level, with measure $dx_0 dx_y/2\pi$:

$$I = \int \frac{dk_x}{2\pi} \int dx_0 \delta I(x_0,y_0,\theta_k). \quad (3.4)$$

There is no dependence of $I$ on $y_0$ because of current conservation.

In zero magnetic field $B = 0 \Rightarrow \gamma = 0$ the dependence of $\delta I$ on $x_0,y_0,\theta$ disappears, so we recover the familiar expression $[23]$

$$I_0 = k_F e \Delta \frac{\pi}{\hbar} \sin(\phi/2) \tan \left( \frac{\Delta \cos(\phi/2)}{2k_B T} \right) \quad (3.5)$$

for the supercurrent in a ballistic Josephson junction. The zero-temperature critical current, reached at $\phi = \pi - 0^+$, is

$$I_{c,0} = k_F e \Delta \frac{\pi}{\hbar}. \quad (3.6)$$

We also require the spatial distribution of the supercurrent density. To avoid notational complexity we assume that there is a one-to-one relation between $k_x \sim (-k_F,k_F)$ and $\theta_k \in (-\pi/2,\pi/2)$. This applies to a warping of the Fermi circle that keeps it singly connected and convex. For a circular Fermi surface the measure $dk_x \mapsto k_F \cos \theta d\theta$. Upon warping we have instead

$$\frac{dk_x}{2\pi} \mapsto \frac{k_F}{2\pi} \rho(\theta) \cos \theta d\theta, \quad (3.7)$$

with a nonuniform angular profile $\rho(\theta)$. The current density can then be written as

$$j_x(x_0,y_0) = \int \frac{dk_x}{2\pi} \delta I(x_0,y_0,\theta_k) \tan \theta_k,$$

$$j_y(x_0,y_0) = \int \frac{dk_x}{2\pi} \delta I(x_0,y_0,\theta_k). \quad (3.9)$$

IV. SUPERCURRENT VORTEX LATTICE

To demonstrate the emergence of a supercurrent vortex lattice we calculate the current density at a point $(x_0,y_0)$ in the normal region, in the limit $W \rightarrow \infty$ that boundary effects can be ignored. (These are considered in the next section.) At a given angle $\theta$ with the $y$ axis (see Fig. 2), the phase shift $\gamma$ in Eq. (3.1) equals

$$\gamma = \frac{2L}{I_{c,0}}(x_0 - y_0 \tan \theta). \quad (4.1)$$

The resulting current density follows from Eq. (3.9) upon integration, once we have specified the relation between $k_x$ and $\theta$. To be definite we take a square lattice dispersion, where $\tan \theta$ is given as a function of $k_x$ by Eq. (2.2). Results are shown in Fig. 3.

If the angular distribution $\rho(\theta)$ on the Fermi surface is peaked at angles $\pm \theta_0$, the phase shift (4.1) produces a bipartite rectangular lattice of vortex-antivortex pairs. (Notice that the superconducting phase difference $\phi$ simply shifts the lattice in the $x$ direction.) The lattice constants are $a_\parallel = a_{\text{vortex}}/2$ parallel to the NS interfaces and $a_\perp = a_{\text{vortex}}/\tan \theta_0$ in the perpendicular direction, with $a_{\text{vortex}}$ given by Eq. (1.1).

In the square lattice the Fermi surface has a square warping near the center of the band, and if the NS interfaces are oriented along a principal axis one has $\tan \theta_0 = 1$, so the vortex-antivortex lattice is a square lattice with lattice constant $a_{\text{vortex}}$ in both directions; see panels (c) in Fig. 3. The two-dimensional lattice disappears—leaving only a single row of vortices—if we move away from band center [see panels (a)], as the angular distribution $\rho(\theta)$ broadens around normal incidence. Since $a_\perp \rightarrow \infty$ for $\theta \rightarrow 0$ this broadening of $\rho(\theta)$ produces a broad range of perpendicular lattice constants, which smear out the structure of the current vortex lattice in the direction perpendicular to the NS interface. Only the $\theta$-independent structure parallel to the NS interfaces remains.

At the elevated temperatures $k_B T \gtrsim \Delta$ of Fig. 3 the vortices and antivortices are equivalent, but at lower temperatures this symmetry between the two sublattices is broken; see Fig. 4. Counterclockwise vortices and clockwise antivortices are centered at points where $\phi - \gamma$ equals, respectively, $\pi$.
or 0, modulo 2\pi. At elevated temperatures the current-phase relationship (3.3) is nearly sinusoidal, with the same slope at \phi = 0,\pi (up to a sign difference). At low temperatures the slope at \phi = 0 is not much affected, so the antivortices retain their circular shape, but the vortices at \phi = \pi see a much larger slope and contract in a square-like shape around the lattice points.

FIG. 3. The six color scale plots show the supercurrent density in a wide Josephson junction, far from the lateral boundaries, for two values of the magnetic field (first and second rows of panels at \( l_m/L = 0.8 \) and 0.32, respectively) and for three values of the Fermi energy (labeled \( a,b,c \) and corresponding to the square-lattice Fermi surfaces at \( E_F/E_0 = 0.2, 0.8, \) and 0.99, respectively). The plots are calculated from Eqs. (2.2), (3.9), and (4.1), at temperature \( k_B T = \Delta / \Delta_2 \). The bottom right panel shows the bipartite current vortex lattice (vortices and antivortices indicated by red and blue dots, lattice constant \( a_{\text{vortex}} = \pi l_m^2 / L = 0.32 \) at \( l_m/L = 0.32 \)) that develops for \( l_m \ll L \) in a square-warped Fermi surface.

V. EDGE RECONSTRUCTION OF THE CURRENT VORTEX LATTICE

The current vortex lattice is modified if we approach the lateral boundaries at \( x = \pm W/2 \). We still assume \( W \gg L \), so we can treat the boundaries separately. At each boundary we impose a hard-wall confinement with specular reflection (see Fig. 2).

A trajectory from superconductor \( S_1 \) to \( S_2 \) that passes through the point \( (x_0, y_0) \) at an angle \( \theta \) with the \( y \) axis is affected by the boundary at \( x = W/2 \) if \( x_0 \) is in the interval

\[
\frac{1}{\pi} W - \frac{1}{\pi} L |\tan \theta| + y_0 \tan \theta < x_0 < \frac{1}{\pi} W.
\] (5.1)

In this interval the boundary reflection replaces the expression (4.1) for the phase shift \( \gamma \) by

\[
\gamma = \beta - \frac{1}{2 L^2 |\tan \theta|} (W - 2 x_0 + 2 y_0 \tan \theta)^2;
\] (5.2a)

\[
\beta = \frac{L W}{L^2} \left( 1 - \frac{L |\tan \theta|}{2 W} \right);
\] (5.2b)

see Appendix A. The corresponding expression for the boundary at \( x = -W/2 \) follows from the symmetry relation

\[
\gamma(x_0, y_0, \theta) = -\gamma(-x_0, y_0, -\theta).
\] (5.3)
The resulting supercurrent distribution near the boundary is shown in Fig. 5. For \( l_m \ll L \) an edge channel appears when the Fermi surface is strongly warped [see panel (c)], becoming less pronounced as the Fermi surface becomes more and more circular; see panels (b) and (a). The streamlines in the edge channel inherit their periodicity from the current vortex lattice, but the width \( w_\text{edge} \approx l_m \) of the edge channel is larger than \( a_\text{vortex} \approx l_m/L \). The net current flowing along the edge channel is sensitive to the phase difference \( \phi \) between superconductors \( S_1 \) and \( S_2 \); see Fig. 6.

To understand this edge reconstruction of the current vortex lattice, we note that because the phase shift \( \gamma \) now depends quadratically rather than linearly on \( x_0 \), there is a point of stationary phase: \( \partial \gamma / \partial x_0 = 0 \) at \( x_0 = y_0 \tan \theta + W/2 \). For a warped Fermi surface with \( \rho(\theta) \) peaked at \( \pm \theta_0 \), an edge channel extends along the lines of stationary phase, of width

\[
w_\text{edge} \equiv 2 |\partial^2 \gamma / \partial x_0^2|^{-1/2} = l_m \sqrt{\tan a_0}.
\]

The edge channel carries a net current from \( S_1 \) to \( S_2 \) that depends on the parameter \( \beta \) and the superconductor phase difference \( \phi \): The edge current is minimal for \( \phi - \beta = 0 \) and maximal for \( \phi - \beta = \pi/2 \), modulo \( \pi \). (In Fig. 6 we have \( \beta \approx 0 \) mod \( \pi \), so minimal and maximal currents correspond to \( \phi = 0 \) and \( \pi/2 \), respectively.) As we will show in the next section, this edge current produces a critical current of order \( w_\text{edge} / W I_c \), with the anomalously slow decay \( \propto 1/\sqrt{B} \).

VI. HIGH-FIELD DECAY OF THE FRAUNHOFER OSCILLATIONS

To obtain the critical current \( I_c = \max_\phi I(\phi) \) of the Josephson junction, we first need to calculate at a given phase difference \( \phi \) the total supercurrent \( I(\phi) \) by integrating \( j_x(x_0,y_0) \) over \( x_0 \) from \(-W/2\) to \( W/2 \). From Eq. (3.8) we thus have

\[
I = \frac{k_F}{2\pi} \int_{-\pi/2}^{\pi/2} \rho(\theta) \cos \theta d\theta \int_{-W/2}^{W/2} dx_0 \delta I(x_0,y_0,\theta).
\]

Analytical progress is simplest in the high-temperature regime \( k_B T \gg \Delta \), when the \( \phi \) dependence of \( \delta I \) from Eq. (3.3) becomes approximately sinusoidal,

\[
\delta I \approx \frac{e \Delta^2}{4 \hbar k_B T} \sin(\phi - \gamma), \quad \gamma = \frac{2e}{\hbar} \int_{S_1} A \cdot d\ell.
\]

We assume that the velocity distribution on the Fermi surface is symmetric around normal incidence, \( \rho(\theta) = \rho(-\theta) \). Because of Eq. (5.3) we may then restrict the \( \theta \) integration in Eq. (6.1) to positive angles,

\[
I = \frac{e \Delta^2 k_F}{8\pi \hbar k_B T} \int_0^{\pi/2} \rho(\theta) \cos \theta d\theta \int_{-W/2}^{W/2} dx_0 \times [\sin(\phi - \gamma) + \sin(\phi + \gamma)].
\]

We thus find that the integrated supercurrent retains a sinusoidal \( \phi \) dependence, with critical current

\[
I_c = I_c \frac{e \Delta^2 k_F W}{4\pi \hbar k_B T}.
\]
In the interval $0 < \theta < \arctan(W/L)$ there is at most one boundary collision. We restrict ourselves to this interval, because the contributions to $I_c$ near grazing incidence are anyway suppressed exponentially at finite temperature. (All contributions in the interval are included in the numerics.) Fixing the arbitrary $y$ coordinate at $y_0 = -L/2$, we have from Eqs. (4.1) and (5.2) the expression for $\gamma$ that we need:

\[
\gamma = \frac{2L}{l_m^2} \left( x_0 + \frac{1}{2} L \tan \theta \right) \quad \text{if} \quad x_0 + L \tan \theta < W/2, \tag{6.5a}
\]

\[
\gamma = \beta - \frac{(W - 2x_0 - L \tan \theta)^2}{2l_m^2} \quad \text{if} \quad x_0 + L \tan \theta > W/2, \tag{6.5b}
\]

with $\beta$ defined in Eq. (5.2b).

The integral over $x_0$ in Eq. (6.4) can be carried out analytically:

\[
I_c = \gamma_{0} \left[ \int_{-W/2}^{W/2} \rho(\theta) \Gamma(\theta) \cos \theta \, d\theta \right], \tag{6.6}
\]

\[
\Gamma(\theta) = \int_{-W/2}^{W/2} \frac{d|x_0|}{W} \cos \gamma = \frac{l_m^2}{W} \sin \beta' + (l_m/W)\sqrt{\pi} \tan \theta [F_C(\alpha) \cos \beta + F_S(\alpha) \sin \beta], \tag{6.7}
\]

\[
\alpha = \frac{L}{l_m \sqrt{\pi}}, \quad \beta' = \frac{\sqrt{\pi} L \tan \theta}{l_m}, \tag{6.8}
\]

The functions $F_C$ and $F_S$ are the Fresnel cosine and sine integrals,

\[
F_C(\alpha) = \int_{0}^{\alpha} \cos \left( \frac{\pi}{2} t^2 \right) dt, \quad F_S(\alpha) = \int_{0}^{\alpha} \sin \left( \frac{\pi}{2} t^2 \right) dt. \tag{6.9}
\]

Both $F_C(\alpha)$ and $F_S(\alpha)$ tend to $1/2$ for $\alpha \to \infty$.

If the angular distribution $\rho(\theta)$ is sharply peaked around $\pm \theta_0$, we obtain from Eqs. (6.6) and (6.7) the high-field ($l_m \ll L$) critical current

\[
I_c(\text{high-field}) = I_{c,0} \frac{w_{\text{edge}}}{W} \sqrt{\pi/2} \left| \sin \left( \frac{\pi}{4} + \frac{L W_{\text{eff}}}{l_m^2} \right) \right|, \tag{6.10}
\]

with effective junction width $W_{\text{eff}} = W - \frac{1}{2} L \tan \theta_0$ and edge channel width $w_{\text{edge}} = l_m \sqrt{\tan \theta_0}$. Comparing with the low-field ($l_m \gg L$) Fraunhofer oscillations,

\[
I_c(\text{low-field}) = I_{c,0} \frac{l_m}{W} \left| \sin \left( L W/l_m^2 \right) \right|, \tag{6.11}
\]

we note three differences: the amplitude decays more slowly, $\propto 1/\sqrt{B}$ instead of $\propto 1/B$; the flux periodicity is larger by a factor $W/W_{\text{eff}}$; and the maxima are phase shifted by $1/4$ flux quantum. This qualitatively different behavior is illustrated in Fig. 7; compare the blue and grey curves.

At the other extreme of an isotropic angular distribution, for a circular Fermi surface, we obtain the opposite effect: instead of a slower decay of the high-field Fraunhofer oscillations the decay is faster, $\propto 1/B^2$ instead of $\propto 1/B$; compare the red and blue curves [24]. This accelerated decay is a known result [18]. What we have found here is that the switch from a circular to a square Fermi surface slows down the decay by a fourth root, from $B^{-2}$ to $B^{-1}/2$.

![FIG. 7. Log-log plot of the critical current $I_c$ versus the flux $\Phi$ through the normal region (aspect ratio $W/L = 10.16$), calculated from Eq. (6.6) for a circular Fermi surface [$\rho(\theta) = 1$, red curve decaying $\propto 1/\Phi^2$], and for a square Fermi surface [$\rho(\theta) = \delta(\theta - \pi/4)$, blue curve decaying $\propto 1/\sqrt{\Phi}$]. The low-field Fraunhofer oscillations (6.11) are included for comparison (grey curve decaying $\propto 1/\Phi$).](094514-6)

### VII. NUMERICAL SIMULATIONS

To test the analytical semiclassical theory we have performed numerical simulations of a tight-binding model. We start from the Bogoliubov–de Gennes Hamiltonian,

\[
H(k) = \left( E(k - eA) - E_F - \Delta \frac{\Delta^*}{\Delta} \right), \tag{7.1}
\]

with the single-particle dispersion $E(k)$ on a square lattice given by Eq. (2.1). The pair potential $\Delta$ and vector potential $A$ are chosen as in Fig. 2, with $\Delta = 0$ for $|\gamma| < L/2$ (no pairing interaction in the normal region) and $A = 0$ for $|\gamma| > L/2$ (complete screening of the magnetic field from the superconductor). The self-field of the currents in the normal region is neglected, so $A$ is entirely due to the externally imposed field $B$. The orbital effect of the magnetic field is fully included, but we neglect the coupling to the electron spin [25] and can therefore omit the spin degree of freedom from the Hamiltonian.

The $2 \times 2$ matrix Green’s function $G(\epsilon) = (\epsilon - H)^{-1}$ is calculated at imaginary energy $\epsilon = i\omega$ using the Kwant toolbox for tight-binding models [26]. The expectation value of the current density in thermal equilibrium,

\[
j(r) = \frac{2e}{\hbar} k_B T \Re \sum_{p=0}^{\infty} \text{Tr} \langle r | G(i\omega_p) | r \rangle \frac{\partial H}{\partial k} | r \rangle, \tag{7.2}
\]

is then obtained from a (rapidly converging) sum over Matsubara frequencies $\omega_p = (2p + 1)\pi k_B T$ [27]. (See Ref. [28] for an alternative approach.)

The time-consuming step in this calculation is the calculation of the inverse operator $(i\omega - H)^{-1}$, but once this is done for one value of the superconducting phase difference $\phi$, we can use Dyson’s equation to obtain the result for other values of $\phi$ without further inversions.

Results for the current vortex lattice in the case of a nearly square Fermi surface ($E_F/E_0 = 0.99$) are shown in Figs. 1 and 8. The agreement with the semiclassical result is not fully quantitative (see Fig. 9), but all the qualitative features of the
vortex lattice coming out of the analytics are well reproduced in the numerics. Also the $1/\sqrt{B}$ decay is recovered in the simulation; see Fig. 10.

In both the analytics and numerics so far we took a ballistic Josephson junction, without any disorder in the normal region, and ideal (fully transparent) NS interfaces. The numerical simulation provides a way to test for the effects of impurity scattering and nonideal interfaces. Disorder was modeled by adding a random component $\delta U$ to the on-site electrostatic potential, drawn uniformly from the interval $[-U_0, U_0]$. For the tunnel barrier we reduced the hopping amplitude at the two NS interfaces. As shown in Fig. 11, the slow $1/\sqrt{B}$ decay persists even if the critical current is reduced substantially by the tunnel barrier. Disorder provides a stronger perturbation, in the form of random sample-specific fluctuations [18], but averaged over series of peaks the slow decay persists.

VIII. 2D LATTICE STRUCTURE IN ORDER PARAMETER AND DENSITY OF STATES

So far we have focused on the current distribution, as a readily observable quantity, but we note that a 2D lattice structure with the same periodicity appears also in the superconducting order parameter $F(r)$ (see Fig. 12 and Appendix B) and in the local density of states $\rho(r, E = 0)$ at the Fermi level (see Fig. 13 and Appendix C).

At the center of a current vortex the absolute value of the velocity field is zero, while the direction of the vector field...
FIG. 11. Effect on the Fraunhofer oscillations of a tunnel barrier at the NS interfaces (a) or of disorder in the normal region (b). The data results from the numerical simulation with the parameters of Fig. 8(b). The disorder strength or tunnel barrier height is quantified by the reduction of the normal state conductance $G$. The topmost (red) curve corresponds to the ideal case without disorder or tunnel barrier.

circulates around it. This definition of a “vortex” does not carry over to the 2D modulation of the order parameter: while the absolute value $|F|$ reaches a local minimum, it remains nonzero at the center of most of the current vortices, as one can see from Fig. 12. The current vortices are therefore not associated with a strictly normal core nor with a $2\pi$ winding of the phase of $F$.

IX. DISCUSSION

Two-dimensional vortex lattices are well established for Abrikosov vortices in a bulk superconductor [1], but Josephson vortices in an SNS junction were only known to arrange as a one-dimensional chain [13,14,16]. Our key conceptual finding is that the 2D arrangement is hidden by angular averaging over the Fermi surface. For a distribution of angles of incidence peaked at $\pm\theta$, resulting from a strong square or hexagonal warping of the Fermi surface, a 2D current vortex lattice develops when the magnetic length $l_m = \sqrt{\hbar/eB}$ drops below the separation $L$ of the NS interfaces. The lattice is bipartite, with a vortex and antivortex in a rectangular unit cell of size $\pi l_m^2/L$ parallel to the interface and $\pi l_m^2/(L\tan\theta)$ perpendicular to the interface. For a circular Fermi surface the 2D lattice degrades to a 1D chain.

It would be interesting to search for this 2D current vortex lattice in some of the quasi-two-dimensional systems that are known to have a warped Fermi surface, such as the hexagonal

\[ l_m/L = 0.32, \ k_B T = 0.05 \Delta, \ E_F/E_0 = 0.99 \]
accumulated along a trajectory across the Josephson junction, from superconductor $S_1$ at $y = -L/2$ to $S_2$ at $y = +L/2$, including the effects of multiple specular reflections at the side walls $x = \pm W/2$. The geometry is shown in Fig. 2. Assume that the trajectory starts at $t = 0$ from the point $x = x(0)$, $y = -L/2$ at the lower NS interface, at an angle $\theta(0) \in (-\pi/2, \pi/2)$ with the positive $y$ axis. The opposite NS interface at $y = L/2$ is reached at the time $t_L = L/v_y$, with $v_y = v_F \cos \theta(0)$ the velocity component in the $y$ direction (which does not change at a boundary reflection).

In the gauge $A = (0, Bx, 0)$ the line integral takes the form

$$\gamma = \frac{2v_y}{l_m} \int_0^{t_L} x(t) dt. \quad (A2)$$

The time dependence of $x(t)$ is given by

$$x(t) = (-1)^{n(t)} [u(t) - v_{tL}(t) W],$$
$$u(t) = x(0) + v_y t \sin \theta(0). \quad (A3)$$

where we have defined $v_{tL} \eq x(0) + L \tan \theta(0) - v_y W$. (A4)

Integration of Eq. (A2) results in

$$\gamma = \frac{1}{l_m^2 \tan \theta(0)} \left( \frac{1}{4} W^2 - x^2(0) + (-1)^{n(t)} \left[ x^2(t_L) - \frac{1}{4} W^2 \right] \right). \quad (A5)$$

This is sufficient to calculate the total current through the Josephson junction, by integrating the current density through the lower NS interface.

To obtain the current distribution within the junction, say at the point $(x_0, y_0)$, we need to find the corresponding coordinates $(x(0), -L/2)$ of the trajectory at the lower NS interface. The angle $\theta$ at the point $(x_0, y_0)$ equals $\pm \theta(0)$. The point $(x_0, y_0)$ is reached at a time $t_0 = (y_0 + L/2)/v_y$ after

$$v_0 = v_{x0} - v_y t_0 \sin \theta = v_{x0} - (y_0 + L/2) \tan \theta$$

boundary reflections. Retracing back the trajectory, we find

$$x(0) = (-1)^{n_L} [x_0 - (y_0 + L/2) \tan \theta - v_0 W],$$
$$\theta(0) = (-1)^{n_L} \theta. \quad (A7)$$

This calculation of the Aharonov-Bohm phase $\gamma$ holds for any number of boundary collisions at $x = \pm W/2$. In the main text we only need the result for a single boundary collision at $x = W/2$. One readily checks that Eq. (A5) reduces to Eq. (5.2) upon substitution of $v_{tL} = 1, v_0 = 0$ for $\tan \theta > 0$ or $v_{tL} = 1, v_0 = 1$ for $\tan \theta < 0$.

**APPENDIX B: TWO-DIMENSIONAL LATTICE STRUCTURE OF THE SUPERCONDUCTING ORDER PARAMETER**

The coherent superposition of electrons and holes in an Andreev level produces a nonzero order parameter $F(r)$ in the normal region, in the absence of any pairing interaction [1]. In this appendix we show that the amplitude $|F|$ has a 2D lattice
structure with the same periodicity as the current vortex lattice studied in the main text.

An Andreev level in the SNS junction of Fig. 2, at the positive energy
\[
\varepsilon = \Delta \cos(\psi/2). \quad \psi = \phi_1 - \phi_2 - \gamma \in (-\pi, \pi).
\]
has a wave function \(\Psi(r)\) that penetrates into the superconducting regions \(|y| > L/2\) over a distance
\[
\xi_e = h \nu_x (\Delta^2 - \varepsilon^2)^{-1/2} = (h \nu_x / \Delta) |\sin(\psi/2)|^{-1}.
\]
In the normal region \(|y| < L/2\) the wave function has a constant amplitude, given in the WKB approximation by [19]
\[
\Psi(r) = \left(\frac{u(r)}{v(r)}\right) = (2 \xi_e)^{-1/2} e^{ik_{\xi}/r} e^{-\xi_{\xi}/2}.
\]
The electron and hole components \(u, v\) differ in phase by
\[
\eta = \frac{1}{2} (\phi_1 + \phi_2 + \gamma) - \frac{2\varepsilon}{\hbar} \int_{S_1} A \cdot dl,
\]  
so that the phase shift \((B4)\) is given by
\[
\eta = \tilde{\phi} - \frac{2\varepsilon x_0 y_0}{l_m^2} + \frac{y_0^2 + \frac{1}{4}L^2}{l_m^2} \tan \theta, \quad \tilde{\phi} = \frac{1}{2}(\phi_1 + \phi_2).
\]

For the warped Fermi surface of a square lattice (unit lattice constant; see Sec. II) we have
\[
\tan \theta = \frac{\sin k_x}{\Xi}, \quad v_y = \frac{E_0 \Xi}{2\hbar},
\]
\[
\psi = \phi_1 - \phi_2 - \frac{2L}{l_m^2} (x_0 - y_0) \sin k_x,
\]
\[
\Xi = \sqrt{1 - (\cos k_x + 2E_0/E_0 - 2)^2}.
\]
The order parameter then results from the integral
\[
F(r) = \frac{\Delta}{2\pi \hbar E_0} e^{-i\hat{\phi}} \int_{-k_F}^{k_F} dk \frac{1}{2\Xi} |\sin(\psi/2)|
\]
\[
\times \tanh \left( \frac{\Delta \cos(\psi/2)}{2\kappa T} \right) \exp \left( -i \frac{y_0^2 + \frac{1}{4}L^2}{l_m^2} \sin k_x \right),
\]  
with \(k_F = \text{arccos}(1 - 2E_0/E_0)\). The resulting 2D lattice structure is shown in Fig. 12, corresponding to the current vortex lattice of Fig. 4.

**APPENDIX C: TWO-DIMENSIONAL LATTICE STRUCTURE OF THE DENSITY OF STATES**

To complete the picture, we also demonstrate the development of a 2D lattice structure in the density of states. The states at \(\pm \varepsilon\) contribute \(\left|\Psi(r)\right|^2 [\delta(E + \varepsilon) + \delta(E - \varepsilon)]\) to the local density of states \(\rho(r, E)\). The total contribution is
\[
\rho(r, E) = \int \frac{dk}{2\pi} \left|\Psi(r)\right|^2 \sum_{\sigma = \pm} \delta(E - \sigma \varepsilon)
\]
\[
= \int \frac{dk}{2\pi} \frac{\Delta}{\hbar \nu_x} |\sin(\psi/2)| \sum_{\sigma = \pm} \delta(E - \sigma \Delta \cos(\psi/2)).
\]
We regularize the delta function by introducing a Lorentzian broadening \(\delta\),
\[
\rho_\delta(r, E) = \int \frac{dk}{2\pi} \frac{\Delta}{\hbar \nu_x} \sum_{\sigma = \pm} \frac{\delta(E - \sigma \varepsilon)}{\varepsilon^2 + \left(E - \sigma \Delta \cos(\psi/2)\right)^2}.
\]  
At the Fermi level, \(E = 0\), we evaluate
\[
\rho_\delta(r, 0) = \frac{2\delta}{\pi^2 E_0 \Delta} \int_{-k_F}^{k_F} dk \frac{\Xi^{-1}}{\delta^2 + \left(E - \Delta \cos(\psi/2)\right)^2}.
\]
The resulting 2D lattice is shown in Fig. 13.

[21] At grazing incidence angles $|\theta| \to \pi/2$ the short-junction criterion is more stringent than $L \ll \xi$, we require $L \ll \xi \cos \theta$. In the analytics we ignore this complication, but it is fully incorporated in the numerics.

[24] The $1/B^2$ decay of the critical current for a circular Fermi surface follows upon numerical integration of Eq. (6.6) with $\rho(\theta) = 1$; see Fig. 7. Unlike the $1/\sqrt{B}$ decay for a square Fermi surface, we have not managed to derive the $1/B^2$ decay analytically.

[25] As explained in T. Yokoyama, M. Eto, and Y. V. Nazarov, Phys. Rev. B 89, 195407 (2014), the influence of the Zeeman energy on the Josephson effect is quantified by the phase shift $\theta = g_{12} B L / \hbar v_F = g_{12} L / \hbar v_F$. In the magnetic field regime where the cyclotron radius $l_{cycl} = m v_F / e B$ is large compared to the separation $L$ of the NS interfaces (which is the regime of interest here), the condition $\theta \ll 1$ is ensured provided the $g$ factor is not much larger than unity.
