High performance motion control of the METIS Cold Chopper Mechanism

Abstract—We present the main results of the performance test campaign of the METIS Cold Chopper Demonstrator (MCCD). This tip/tilt mirror, which operates at a temperature of 77K, is one of the critical components in the Mid-Infrared E-ELT Imager and Spectrograph (METIS) for the European Extremely Large Telescope (E-ELT). The performance requirements of the MCCD relate to the field of fast and very accurate reference tracking. We discuss the applicability of different high performance motion control strategies and describe the control synthesis of a repetitive and of a novel hybrid controller. We identified the presence of non linearities in the plant, which limits the performance of the hybrid controller. The repetitive controller shows very promising results and can handle the non linearities in the system. This experimental phase concludes the MCCD program, which was initiated to verify the feasibility of a high performance cryogenic tip/tilt mirror at an early stage in the METIS development. Because of the very promising test results, no significant changes to the hardware will be implemented. We believe that minor adjustments will suffice to meet all requirements of the final hardware after integration with the METIS instrument.

Index Terms—high performance motion control, hybrid control, repetitive control, control synthesis, hysteresis, tip/tilt mechanism

I. INTRODUCTION

The METIS Cold Chopper (MCC) mechanism is one of the critical components in the Mid-Infrared E-ELT Imager and Spectrograph (METIS) [1] for the European Extremely Large Telescope (E-ELT) [2]. With its 39m dish, the E-ELT will be the largest optical/infrared telescope ever. The E-ELT will see first light in 2024 and is being developed by the European Southern Observatory (ESO).

METIS will be one of the first three scientific instruments on the E-ELT, covering the thermal infrared wavelength range. At these wavelengths, very accurate subtraction of the spatially and temporally varying background is essential. This is usually done by beam chopping, i.e., alternating the optical beam between science target and a reference location on the nearby sky at a frequency of a few Herz. While the beam chopping is traditionally done by the telescope’s secondary mirror, this option does not exist for the E-ELT and an alternative solution within METIS had to be found.

This work is part of the MCC demonstrator (MCCD) project, which was initiated to show the feasibility of a high performance chopping mirror inside a cryogenic instrument at an early stage in the METIS development. The MCC is a tip/tilt mirror at the pupil position of METIS. Tilting the MCC in two dimensions moves the orientation of the telescope beam on the sky without having to move the telescope.

Different chopping and scanning strategies can be considered [3]. The focus here is on the so called chopping or beam switching technique, where the mirror quickly chops between two or more exactly reproducible mirror positions. From differential measurements the sky background and detector noise can be derived and subtracted from the image which contains the source.

Several challenging performance requirements drive the design of both hardware and control of the MCC (see Table VII of Section IV). Most notably are the requirements for short beam switching times (i.e., high observing efficiency with small overheads, which requires short settling times) and very accurate positional repeatability (which is required for sharp images in co-added, long term exposures). Meeting these requirements simultaneously is very challenging from a control perspective, which is related to the field of high performance motion control.

Different control strategies are available for high performance motion control of nano positioning mechanisms. What these techniques generally have in common is the application of a feedforward (FF) signal for fast stepping, typically but not necessarily in parallel with a feedback controller for noise reduction and robustness. Although the design of this FF signal is usually based on the available knowledge of the plant dynamics (model based approach), the details about the generation of the FF signal [4] [5] and the shaping of the reference profile [6] [7] can vary a lot.

When reference profiles of a repetitive nature are applied, as for this application, one can also consider the use of a repetitive controller [8] [9]. Different from the model based
approach, the repetitive loop generates the FF signal by learning with every repetition.

We developed a hybrid control strategy [10], [11] which applies a FF input in open loop during the step, to avoid possible negative effects of the closed loop controller because of its limited bandwidth w.r.t. the frequency content of the reference profile as discussed in [10], [12], and switches to closed loop during the observation periods. The method involves resetting, memorizing and switching between different sets of control states at fixed moments during an observation. Resetting of the control states is similar to reset control [13] and impulsive control [14], where the state of a feedback controller is subject to sudden changes dictated by the reference profile or the tracking error. A clear distinction with our method however is the definition of the initial control states at the start of every observation period and that we perform the step in open loop. We compare the experimental results applying this strategy with that of a repetitive controller and discuss the different issues related to both methods.

In Section II we describe in detail the system identification of the hardware, which revealed the presence of hysteresis in the system. The applied control strategies are described in Section III and the experimental results are given in Section IV. We discuss some of the issues regarding the implementation of the control strategy in Section V and the conclusions of the test campaign are given in Section VI.

II. SYSTEM IDENTIFICATION

A. Hardware and test setup

For details about the MCCD mechatronic design the reader is referred to [15]. Here we summarize the key mechatronic elements of the mechanism and describe the experimental test setup. Details about the dynamical behaviour of the system are given in Section II.B.

A schematic overview of the MCCD mechanism, which is designed to operate in cryogenic conditions, is shown in Fig. 1. It has 3 Degrees of Freedom (DoF), which composes of rotation around the x and y-axis (tip/tilt) and translation along the z-axis. The triangular support structure with the circular mirror body is supported by 3 monolithic struts with elastic hinges to constrain the 3 undesired DoF’s without introducing backlash or friction. Displacements are measured by 3 Attocube position sensors (type: FPS3010) based on the principle of laser interferometry and actuation is provided by 3 voice coil actuators. These voice coil actuators were specially developed for the MCCD. In the design the back iron is detached from the permanent magnet. It is fixed to the base structure which limits the amount of moving mass (magnet only) of the actuator and therefore considerably reduces the moment of inertia of the mirror body.

The mechanism dynamics (inertia, spring constant and damping) are designed to be rotationally symmetric. The multiple-input multiple-output (MIMO) system is converted to three decoupled single-input single-output (SISO) systems by applying the following matrix transformations.

\[
\begin{bmatrix}
\theta_1 \\
\theta_2 \\
\theta_3
\end{bmatrix} =
\begin{bmatrix}
\frac{2}{3}y & 1 & \frac{1}{3}
\\
\frac{2}{3}y & -1 & \frac{1}{3}
\\
\frac{2}{3}y & 0 & \frac{1}{3}
\end{bmatrix}
\begin{bmatrix}
\tilde{z}_1 \\
\tilde{z}_2 \\
\tilde{z}_3
\end{bmatrix}
\]

(1) relates the three sensor readouts \((\tilde{z}_1, \tilde{z}_2, \tilde{z}_3)\) to the three DoF’s of the system, where \(r_s\) is the radial distance of the sensors to the heart of the mirror. (2) converts the control inputs \((F_z, M_{\theta_1}, M_{\theta_2})\) for the different DoF’s, to the individual force inputs \((F_1, F_2, F_3)\) of the actuators. Here \(r_f\) is the radial distance of the actuators to the heart of the mirror.

The experimental setup is sketched in Fig. 2. Tests are performed in a cryostat at an operating temperature of 77K. The sensor electronics are placed outside the cryostat. The optical measurement signal is guided to the MCCD hardware by 3 glass fibers. Calibration of the 2 DoF rotational motion is performed using a theodolite. The Matlab xPC target platform is used to implement the digital controller (designed in Matlab Simulink using a host PC) on a target machine. The system runs at a sampling rate of 10 kHz.

![Schematic overview of the MCCD mechanism.](image)
plot. We only use the magnitude plot for model fitting because of the limited accuracy of the phase information.

Fig. 3 shows the bode magnitude plot of the open loop plant for \( \theta_y \). The dominant resonance frequencies of the mechanism are clearly visible. Table I gives these dominant resonance frequencies and compares them to the results from a detailed Finite Element Analysis (FEA) [16].

The resonant behaviour at approximately 500Hz cannot be explained by the mechanism dynamics. The same is true for a small, but relevant resonance at 125Hz. These resonances do not show up in the FEA and, despite the rotational symmetry of the MCCD, are not present in the \( \theta_y \) dynamics. They are believed to originate from the test setup e.g., the cryostat, whose structural dynamics are not symmetrical w.r.t. the introduced forces as a result of \( \theta_x \) or \( \theta_y \)-rotation.

Due to the influence of the cryostat, we consider a non collocated lumped mass system as shown in Fig. 4 to describe the \( \theta_y \)-dynamics. This results in an \( 8^{th} \)-order system with 5 stable zeros, i.e. 2 complex conjugated pairs close to respectively the 125Hz and the 500Hz resonance and one zero at high frequency. Based on this system, we model the \( \theta_y \)-dynamics including the dominant resonance at 29.6Hz, a skew notch at 125Hz and at 487Hz and a broad resonance at 1440Hz (to account for the two sharp resonances between 1.4 and 1.5kHz). The high frequency zero has very limited influence on the system response and we choose to ignore this in our system model.

The \( \theta_y \)-dynamics are modelled as a \( 4^{th} \)-order plant excluding the two resonances related to the cryostat. Finally, the \( z \)-dynamics are less critical and can be approximated by a \( 2^{nd} \)-order plant.

Using the transfer function given by:

\[
P(s) = \frac{a_0 s^n + a_{n-1} s^{n-1} + ... + a_1 s + a_0}{b_0 s^n + b_{n-1} s^{n-1} + ... + b_1 s + b_0}
\]  

(3)

where \(a_0, ..., a_n, b_0, ..., b_0\) are coefficients to be fitted, the final system models for the different DoF’s are given in Table II.

Comparison of the simulated step response with experimental data shows a good match for the 1 mrad chop range for which the identification has been performed (see for example Fig. 7 (0° offset result)).

A detailed system model, including the weak resonance at 125Hz is required for an accurate FF design. This is discussed in more detail in Section III-A.

### C. Non linear behaviour

The experimental results revealed the presence of non negligible non linearities in the system. This is shown in Fig. 5 where the linear component of the system response is taken out to clearly expose a slightly deformed hysteresis curve. The hysteresis is caused by the relative displacement of the constant magnetic field, generated by the permanent magnet, with respect to the back iron in the actuators. As a result, the magnetic field strength, at any point in the back iron, depends on the orientation of the chopper, and the back iron material exhibits its magnetic hysteresis curve when the mirror is rotated.
The slight deformation of the hysteresis curve is caused by the position dependent reluctance in the magnetic circuit. The reluctance is maximal in the center position ($\theta = 0$) and reduces with increasing angle. This introduces negative magnetic stiffness. As the reluctance of the magnetic circuit is inversely proportional to the magnetic field strength, it also makes the force constant of the actuator position dependent. In Section III-A we describe the hybrid control method. It includes the design of a feedback controller and of a FF signal. The non linearity has only a small effect on the response of the deformation of the hysteresis curve. Fig. 6 shows the basic building blocks of the non linear MCCD model. Both operators use the angular orientation of the mechanism as input parameter and affect the input ([N.m]) to the linear plant model.

It is known that tuning the JA model parameters is a difficult process which is strongly dependent on the choice of initial conditions and often results in non ideal solutions [18]. As we have to include 6 extra parameters in our model to also account for the non linearity, related to the positional dependent force constant of the system, tuning of the complete set of parameters becomes even more of a challenge. We tuned the parameters by hand, after which we used Matlabs non linear curve fitting procedure (lsqcurvefit) for fine tuning. This, however, did not result in further optimization of the parameters.

The tuned model parameters are given in Table III. The model response is included in Fig. 5. The fit shows the same characteristic response to a sine input for different amplitudes. The accuracy of the model is however limited. This is supported by the experimental results given in Fig. 7, showing the response of the system to a FF-input applied at different offset positions in the chop range. The FF input was generated on the basis of the linear model and designed to deliver a 1 mrad step. The response of the linear model (blue line) is independent of the offset position in the chop regime while the experimental result clearly shows the dependence on start position, which indicates hysteresis phenomena have taken place. This hypothesis is corroborated by the simulation result when we include the hysteresis model.

The non linear plant model provides valuable insight in the non linear behaviour of the MCCD hardware and fully explains all observed effects. However, from a control design perspective, as the model complexity drastically increases when the hysteresis model (with its 12 parameters) is included, and as the accuracy of the modelled response is limited, we decided not to use the non linear model for the FF design.

### III. CONTROL SYNTHESIS

#### A. Hybrid controller

In this paper we will implement a hybrid controller based on [10], [11]. As the proposed strategy requires switching of the system between feedforward and feedback control, which involves resetting, memorizing and switching between different sets of control states at every start of a scanning period, proof of output regulation is not trivial. The structure

![Fig. 3. Bode magnitude plot of $\theta$. Experimental data and fitted 8th order model. Experimental data based on sinesweep (Freq. range 5-600 Hz and 1400-1500Hz covered with 5Hz frequency resolution. Other regime covered with 50Hz res.)](image)

![Fig. 4. Non collocated lumped mass system representative for the dominant 8th-order $\theta$-dynamics. The actuator force is applied at the triangular support structure and displacements are measured at the mirror surface relative to the MCCD base frame.](image)

![Fig. 5. Tuned parameters of non linear MCCD model. NB: The $k_c$ parameter is not part of the JA model.](image)
of the controller and the results on hybrid output regulation [19] motivated us to formulate the complete system in the hybrid framework. To illustrate this we recall the basic theory from [10], [11].

A hybrid system is a system which exhibits both continues time and discrete time dynamics denoted respectively as flow and jump dynamics. We utilize the hybrid formalism and notation as given in [20].

**Hybrid system formulation and control design criteria**

For compactness the 1 Degree of Freedom (DoF) dynamics are formulated. Extension to higher dimensions is however trivial as the MCCD is rotationally symmetric and the \( \theta \) dynamics are decoupled.

The plant dynamics of the MCCD can compactly be formulated as:

\[
\begin{align*}
\dot{x} &= A_Gx + B_Gu, \quad x(t_0) = x_0 \quad \forall (x,u) \in \mathbb{R}^n \times \mathbb{R}, \\
y &= C_Gx,
\end{align*}
\]

(4)

Where \( A_G, B_G \) and \( C_G \) are the state space matrices which realize the transfer function in (3). The input \( u \) represents the current input signal to the actuator and the output \( y \) is the measured angular displacement.

Observe that by applying \( u_j \) to (4) for any arbitrary initial state \( x_j \) and initial time \( t_j \), we have

\[
x(t_j^+) = M_Gx(t_j) + N_j \quad \forall j \in \mathbb{N},
\]

(5)

where the plant transition matrix \( M_G := \exp(A_Gt_j) \) and

\[
N_j = \int_{t_j}^{t_j^+} \exp(A_G(t_j^+ - \lambda))B_Gu_j(\lambda) \, d\lambda.
\]

Eq. (5) resembles the jump dynamics in the hybrid system framework. Thus if we apply the input signal \( u_j \) at the time interval \( t \in [(j + 1)t_{obs} + t_j, (j + 1)(t_{obs} + t_j)] \), where \( t_{obs} \) defines the length of the observation period between two consecutive steps and \( t_j \) is the step time, then the dynamics of the plant can be rewritten in the hybrid systems formulation by first defining the hybrid time domain \( E \) as follows:

\[
E := \bigcup_{j \in \mathbb{N}} \{ (j + 1)t_{obs}, (j + 1)(t_{obs} - t_j) \} \times \{ j \}.
\]

The dynamics of \( x \) on \( E \) can equivalently be described by the following hybrid system

\[
\begin{align*}
\tau_c &= 1 \\
\zeta &= A_G\zeta + B_Gv, \quad \zeta(0,0) = \zeta_0 \\
&\quad \forall (\tau_c, \zeta, v) \in [0, t_{obs}] \times \mathbb{R}^n \times \mathbb{R} \\
\tau_c^+ &= 0 \\
\zeta^+ &= M_G\zeta + N_j \\
y &= C_G\zeta,
\end{align*}
\]

(6)

where \( \zeta_0 = x(0) \), \( v \) is the additional control signal applied during the flow periods and \( \tau_c \) is a clock variable with a dwell time \( t_{obs} \) which defines the moment of jumping of the system.

This reformulation of the plant dynamics into hybrid setting opens the possibility of assigning optimal control solutions during the first \( t_j \) seconds (which are computed off-line for the nominal positions) and implementing a hybrid feedback controller to stabilize the system.

Following the hybrid output regulation setting as in [19], we can adopt the following exosystem which generates the reference signal \( r \) and is also defined on the hybrid time domain \( E \) as above

\[
\begin{align*}
\dot{\tau_c} &= 1 \\
\dot{w} &= Sw, \quad w(0,0) = w_0 \quad \forall (\tau_c, w) \in \mathcal{W} \\
\tau_c^+ &= 0 \\
w^+ &= Jw \quad \forall (\tau_c, w) \in \mathcal{W} \cap \{ t_{obs} \} \times \mathbb{R}^n \\
\dot{r} &= Qw,
\end{align*}
\]

(7)
Finally with the final model principle as in [19], the hybrid controller can now be reduced to the following form:

\[ S = \begin{bmatrix} Y & 0 \\ 0 & 0 \end{bmatrix}_{(4q \times 4q)} \quad Y = \begin{bmatrix} 0 & \omega_n & 0 & 0 \\ -\omega_n & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix} \]

\[ J = \begin{bmatrix} 0 & I_{(4q(q-1))} & 0 \end{bmatrix} \]

\[ M_e = \exp(\Gamma \cdot t_{obs}) \]

\[ Q = \begin{bmatrix} 1 & 0 & 1 & 0 & 0 \end{bmatrix}_{(1 \times (4q(q-1))} \]

and

\[
\begin{align*}
& w = [w_1 \quad w_2 \quad \ldots \quad w_q] \\
& w_p = [w_{p1} \quad w_{p2} \quad w_{p3} \quad w_{p4}] .
\end{align*}
\]

Finally \( \mathcal{W} := \{(\tau_c, w) : \tau_c \in [0, t_{obs}], w \in W(\tau_c)\}, \) where the set valued mapping \( \tau_c \rightarrow W(\tau_c) \subseteq \mathbb{R}^q \) is continuous with compact values. The parameter \( q \in \mathbb{N} \) defines the number of integration periods that constitute a single repetition of the reference profile. \( p \in \{1, 2, \ldots, q\} \) and \( \omega_n \) is the angular velocity of the oscillator. The matrix \( M_e \) is the transition matrix related to \( Y \). The presence of the inverse of this term in the jump matrix guarantees that the active exo-state variables are reset to their initial state after every period of flow, even if \( t_{obs} \neq 2\pi/\omega_n \).

The exosystem can generate all astronomical observation modes that are discussed in [3], except for spiral chopping, by choosing the appropriate initial conditions \( w_0 := w(0,0) \) in combination with the required form of \( N_j \) to jump between the different flow sets.

NB: For the current application we only consider square wave chopping which greatly simplifies the exosystem description. We present the full description here to illustrate the necessity to reset the control states at the end of each flow period. For square wave chopping \((q = 2)\) the matrices can be reduced to the following form:

\[
S = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix} \quad J = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \quad Q = \begin{bmatrix} 1 & 0 \end{bmatrix}
\]

where

\[
A_C = \begin{bmatrix} * & 0 \\ 0 & S \end{bmatrix}
\]

\[
B_C = \begin{bmatrix} * & k_1 & 0 & k_2 & k_3 & 0_{(1 \times (4q(q-1)))} \end{bmatrix}^T
\]

\[
C_C = \begin{bmatrix} * & Q \end{bmatrix} \quad D_C = \begin{bmatrix} * \end{bmatrix}
\]

\[
\Phi = \begin{bmatrix} I_s & 0 \\ 0 & J \end{bmatrix} \quad \Psi = \begin{bmatrix} * \\ 0 \end{bmatrix}
\]

the parameters \( k_1, k_2 \) and \( k_3 \) are controller gains. The elements in * are related to the design of a robust feedback controller and can be designed according to each different application. The identity matrices in \( \Phi \) indicate that the states related to * are not changing as a result of the jump. The \( J \) in the \( \phi \) matrix is identical to the jump matrix of the exosystem. Again the inverse of \( M_e \) guarantees that in the steady state, the active control states related to the internal model jump back to the correct initial state at the end of the flow period. The variable \( e \) is the error signal, i.e., \( e = r - C_G \xi \). Again this general form can be reduced to the special case of square wave chopping by applying (8) and reformulating the input matrix as \( B_C = [\star \quad k_1 \quad 0] \).

Finally, the complete closed loop hybrid system is given by:

\[
\begin{align*}
\dot{\xi}_c &= 1, \\
\dot{w} &= Sw, \\
0 &= w(0,0) = w_0 \\
(\xi, \xi, e) &\in \mathbb{Q} \times \mathbb{R}^m \times \mathbb{R} \\
(\tau_c, w, e) &\in \mathbb{W} \times \mathbb{R}^q \times \mathbb{R}^m
\end{align*}
\]

(10)

with

\[
\mathcal{H}_c := \begin{bmatrix} A_G - B_G C_G & B_G C_C - B_C G_C \\ -B_C G_C & A_C \end{bmatrix} \quad \mathcal{L}_c := \begin{bmatrix} B_G D_C Q \\ B_C Q \end{bmatrix}
\]

\[
\mathcal{F}_c := \begin{bmatrix} M_G \\ -\Psi C_G \end{bmatrix} \quad \mathcal{M}_c := \begin{bmatrix} N_w \\ \Psi Q \end{bmatrix}
\]

where \( N_j \) is related to the exo-state through \( N_{w_j} \), i.e., \( N_j := N_{w_j} \).

Based on this reformulation of the plant dynamics in the hybrid system framework, we can define the chopper scanning control problem as follows:

**Chopper scanning hybrid control problem**: Design a hybrid controller (9) for the hybrid plant (6) such that the closed-loop system (10) has bounded trajectories and \( \lim_{t \rightarrow \infty} e(t, j) = 0 \) uniformly.

The following result defines necessary and sufficient conditions to solve the chopper scanning hybrid control problem.
This can be used for synthesis of the hybrid controller with the considered plant dynamics.

Let $\phi_{cl}$ be the state transition matrix of the flow dynamics

$$
\begin{bmatrix}
\xi
\end{bmatrix} = \mathcal{H}_{cl}^{i} \begin{bmatrix}
\xi
\end{bmatrix}.
$$

In other words $\phi_{cl}(t_{obs}) = \exp(\mathcal{H}_{cl}t_{obs})$ and $\phi_{cl}(t_{0}) = I_{n+m}$.

**Proposition 3.1:** Assume that the restriction of $\mathcal{H}_{cl}$ to the active subspace is Hurwitz. Then there exists an attractive invariant manifold $\mathcal{H}$ such that $Qw - CG\xi = 0$ if and only if

$$
\gamma := \sigma_{\text{max}} \left( \prod_{h=0}^{l-1} \mathcal{J}_{cl(i_{h}, j_{h})} \phi_{cl}(t_{obs(i_{h}, j_{h})}) \right) < 1, \tag{11}
$$

where $\sigma_{\text{max}}$ is the largest eigenvalue of the matrix and $l$ is the number of scans contained in the smallest repeating sequence of scans with different $t_{obs}$. In particular, we have that $e = r - CG\xi \to 0$ as $t \to \infty$.

If we satisfy condition (10), the plant asymptotically converges to the invariant manifold which satisfies zero error tracking (this also implies a bumpless transition when switching between feedforward and feedback control).

For a detailed description of the hybrid control method and for the proof of output regulation the reader is referred to [10], [11].

A typical timeline for square wave chopping, applying the hybrid control strategy, is given in Figure 9. Indicated are the periods where feedforward or feedback control is applied. The arrows visualize the reset and memory actions. **Simulation results of MbFF vs hybrid stepping**

To illustrate why we perform the step in open loop, we simulated the effect of the step time of the reference profile on the settling time of a second order plant for the MbFF and the hybrid strategy. For completeness we also included the result when applying the feedback loop without the FF path. The FF signal is based on an inverse plant model which exhibits frequency dependent inaccuracies. We applied a PID controller which was tuned for a certain bandwidth and limited overshoot of the closed loop plant. The different configurations studied are summarized in Table IV. For clarity the effect of noise and disturbances is excluded from the results as, for the field of nano positioning, this will typically affect the positional stability of the plant before it has a significant effect on settling time. Plant constraints are not considered in the simulation.

Figure 8 shows the results of the simulations. The hybrid controller outperforms the MbFF for fast reference profiles. For slower reference profiles the closed loop improves the tracking of the reference and the MbFF approach shows slightly better results. As can be expected, increasing the closed loop bandwidth reduces the settling time.

The results vary with every specific configuration, but generally speaking it can be concluded that for fast reference profiles, with respect to the typically limited controller bandwidth, open loop stepping performs better.

**Design of FF input $u_j$**

![Fig. 8. Effect of step time of reference profile on settling time of system configurations studied in Table IV for the hybrid, MbFF and closed loop only control strategies (Left: results for conf. 1 and 2. Right: results for conf. 3 and 4). The relative settling is defined as the settling time of the plant normalized by the applied reference step time. The Hybrid 100 and 173 results largely overlap because of the limited influence of the PID controller after the step (as a result of the very small error signal).](image)

The FF signal is generated by applying quadratic programming to the following optimization problem with input constraints

$$
\min_{u_j \in U} \| x_d(t_k) - x(t_k) \|_2 \tag{12}
$$

where $U$ is the set of allowed control inputs $U := \{ u_j \in \mathbb{R}^n : |u_{j_1}| \leq 4.2N.m \}$. $x_d(t_k)$ is the desired plant state at the end of the step (at time $t_{k}$) and $x(t_k)$ is the realized end state as a result of the discrete FF input sequence. This approach can handle input constraints and deals with the discrete nature of the FF input naturally.

We recognize that, because of the high frequency reference signal in relation to the typically limited bandwidth of the closed loop controller, fast settling can only be achieved by accurate FF design and not by error convergence after switching to closed loop. Therefore, we use the full 5 msec settling time specification for our FF signal. This maximizes...
feedback controller shows the necessity to include the higher order resonances in the MCCD plant model (including only the 26 Hz rigid body mode) to different model plant configurations. This clearly shows the necessity to include the higher order resonances in the FF-design.

Feedback controller

The feedback controller for $\theta_1$ has been tuned by loop shaping. It consists of a skew notch filter, to compensate the large phase shift introduced by the dominant resonance at 29.6 Hz, an integrator, required for constant reference tracking and a first order low pass filter for high frequency cut off. The complete controller, discretized by the Tustin method, is then given by:

$$C_0 = \frac{0.1722z^4 - 0.3337z^3 - 0.01048z^2 + 0.3337z - 0.1617}{z^4 - 3.311z^3 + 4.085z^2 - 2.228z + 0.4531}$$

In Fig. 10, the bode plot of both the sensitivity function $S = (1 + PC)^{-1}$ and the complementary sensitivity function $T = PC(1 + PC)^{-1}$ of the closed loop plant are given. T shows good tracking ability at low frequencies. $S$ was tuned for sufficient amplifier noise and disturbance attenuation below 100 Hz. The slight peaking of the Bode magnitude plot of $S$ above 200 Hz (max. of 4dB at 500Hz) is allowed because of the low sensor noise in the system. The gain and phase margins of the closed loop system are respectively 14.3 dB and 82°, from which we can conclude that the feedback loop is robustly stable. The value of $\gamma$, as defined in (11), is 0.36, so we satisfy the necessary and sufficient condition for output regulation of the hybrid controller.

Because of the symmetry in the system, and because we do not specifically shape the 125Hz and 487Hz resonances, the same controller can be applied to the $\theta_2$ DoF. For the control of the $z$-displacement it suffices to apply a discrete PID controller with $k_p = 89$, $k_i = 1000$ and $k_d = 0.56$ with a 4012.6 filter bandwidth (Forward Euler discretization method).

Table V

Influence of plant resonances on settling when applying a FF signal based on the 2nd-order plant model for a step from $\theta = 0$ to 8.5 MRAD. The resonances considered in the different plant models are given in the table. NB: The complete 8th-order plant also settles within 4.9 msec when applying a FF signal based on the 8th-order plant model.

Fig. 10. Bode plot of complementary sensitivity (T) and sensitivity function (S) of closed loop plant for $\theta_1$.

B. Repetitive controller

Fig. 11 shows the repetitive control layout. The repetitive loop is placed in parallel with the feedback controller described in Section III-A. The repetitive loop consists of a so called L-filter for phase compensation, a Q-filter to add robustness and an internal model which can generate any repetitive signal with period $N$.

The learning update law of the repetitive loop can be formulated as follows:

$$z^N U_r(z) = Q(z) U_r(z) + z^2 L(z) k_r E(z), \quad (13)$$

where $z^N U_r(z)$ is the new input which will be applied during the next repetition and is constructed from the input of the current repetition $U_r(z)$ and from the error $z^2 E(z)$ as a result of this input. From the feedback loop we have

$$E(z) = -S_p(z) U_r(z), \quad (14)$$
where $S_P = P/(1+PC)$ is the plant sensitivity function. Combining (13) and (14) gives us

$$z^NE(z) = Q(z)(1-z^2S_P(z)k_rL(z))E(z),$$

which can be interpreted as the error propagation with every repetition, from which it can directly be concluded that the error converges monotonically if $|Q(1-z^2S_P(z)k_rL)| < 1$ for all frequencies up to the Nyquist frequency. Taking $L = S_P^{-1}, k_r = 1$ and $\gamma = 0$ theoretically delivers perfect tracking after only one iteration (dead-beat solution). However, an exact inverse is typically not realizable as the inverse of $S_P$ often is non proper or even unstable as a result of respectively a proper or non minimum phase $S_P$. Different techniques, such as ZPETC [21], are available for the design of $L$, but the matrix is typically not exact and plant uncertainties and non modelled dynamics further limit the accuracy of the filter design. The lead term $z^\gamma$ can be used to partly compensate for the phase lag introduced by the non ideal $L$-filter as described in [9]. The $Q$-filter can be designed as a low pass filter to allow for monotonic error convergence but this comes at the cost of reduced tracking performance.

The reproducibility is generally considered to be a measure for the tracking accuracy that can be attained by repetitive control. The reproducibility of the MCCD for chopping is $\Delta \theta < 10\mu$rad during the step and $\Delta \theta < 2\mu$rad during the integration periods.

In our experiment, as we are interested to explore the maximum settling performance using the repetitive method, we take $Q = 1$. This allows for maximum error reduction at the cost of monotonic convergence. We avoided inversion of $S_P$ but used an inverse of the $4^{th}$-order $\theta_r$-dynamics of the plant as our $L$-filter, where we added a $4^{th}$-order Butterworth filter to make the transfer function proper. We are aware that sampling of a continuous time system may lead to the introduction of RHP zeros in the discrete model [22], which in turn can cause problems during system inversion. To avoid this problem we designed the filter in continuous time, after which the $L$-filter was discretized by the Tustin method. The resulting filter is then given by:

$$L = \frac{0.048z^4 + 6.253e - 5z^3 - 0.096z^2 - 2.939e - 5z + 0.048}{z^4 - 3.187z^3 + 3.876z^2 - 2.124z + 0.441}.$$  

To avoid interference between the feedback controller and the repetitive loop we only close the loop after convergence of the repetitive controller.

Because of the good match between the model and the hardware, we could tune $k_r$, $\gamma$ and the cut off frequency of the Butterworth filter offline, and no adjustments of the parameters were needed when we applied the method to the real hardware. NB: The good quality of the learned step input does not introduce significant oscillations after the step. This and the large stability margins of the feedback loop, allowed us to further increase the gain of the feedback controller for better amplifier noise and disturbance attenuation. The tuned parameters are given in Table VI. The gain of the feedback controller was increased by a factor of 1.5.

The reference profile for chopping is generated by applying the method described in [23]. This method generates a smooth $4^{th}$-order reference profile while taking into account the limits (maximum jerk etc.) of the plant.

In Fig. 12 the good match between the simulation and the experimental results is shown. After about 2.4 seconds (12 iterations) the repetitive controller has converged. The effect of activating the feedback controller after 4.7 seconds is clearly visible.

The compensator for $\theta_r$ is very similar but here the resonances of the $L$-filter are matched with the 29.6Hz and 1440Hz resonances of $P_h$.

![Fig. 12. Comparison of simulation result with experiment when tracking a 5Hz chopping reference between 0 and 8.5 mrad in $\theta_r$. Error convergence from 1 sec onwards is shown. Feedback controller is activated after 4.7 sec.](image)

We use a practical approach for our repetitive controller design to be able to study its general performance without the need for $S_P$ inversion of the high order plant described in Table II. We are aware that small changes in the response can occur when applying a (zero phase) $Q$-filter and inversion of $S_P$. However, for $\theta_r$ the tracking error is in the order of the reproducibility of the system which means that for this DoF no further improvements can be made. The performance of the repetitive controller is discussed in Section IV. Some considerations about the implementation of the method on the final MCC hardware are discussed in Sections V and VI.
IV. EXPERIMENTAL RESULTS

All tests are performed with the test setup as described in Section II.A. Table VII summarizes the most important test results. All results, except for the settling time are generated applying the hybrid controller. As we use the same feedback controller, most results are applicable to both control strategies. It is well known that the influence of stochastic disturbances (system noise and external vibrations) are amplified by the repetitive method [24]. Because of this the positional stability is worse than for the hybrid approach. However, as discussed in Section III.B, we could compensate for this effect by increasing the loop gain of the feedback controller.

Most requirements are satisfied but the positional stability specification and the settling time are not fully met. We believe that the positional stability can be further improved by fine tuning of the feedback controller in the final setup (when the exact noise and disturbance levels on the E-ELT platform are known), and by reduction of the amplifier range as discussed in Section III-A. In [25] the effectiveness of different strategies to reduce the negative influence of stochastic disturbances on positional stability when applying a repetitive controller is investigated. If required this approach can be considered to further reduce the influence of stochastic disturbances on the positional stability of the plant.

The settling time results given in Table VII are generated by the repetitive controller. Fig. 13 shows the result of chopping in \( \theta \), between 0 and 8.5 mrad for both the hybrid and repetitive method. The hybrid controller converges within 1 chop cycle. The repetitive controller takes about 9 cycles but the settling time is much better. This is illustrated in Fig. 14 where a close up of the settling behaviour at the 8.5 mrad position after convergence is given. Since an observation typically takes minutes, the time required for learning (approx. 2 sec) is easily compensated by the much better settling performance of the repetitive controller.

As discussed in Section II.C, the quality of the FF signal applied in the hybrid method is limited as a result of the non modelled non linearity in the system. This limits the performance of any model based FF method. As argued in [9], the linear repetitive controller can deal with the small non linearity in the system and there is no need for adding extra complexity by applying a non linear repetitive controller.

The difference in the settling time for \( \theta \) and \( \theta \) can be explained by the resonant behaviour of the experimental setup at approximately 500Hz, which is only present in the \( \theta \)-dynamics. Including the modelled resonance at 500Hz in the \( \theta \)-filter design for \( \theta \) did not improve performance because of the limited accuracy of the modelled resonance. More detailed modelling is required to correctly compensate for this effect in the \( \theta \)-filter design, but, as the resonance is part of the test setup and not of the MCCD hardware, we did not put further effort into solving this issue. Instead the issue was taken up with the design engineers of the METIS team recommending to avoid low frequency resonances in the structural interface of the MCC with the METIS instrument.

When applying the repetitive controller we ignored the typical design rule of monotonic error convergence (\( |Q(1 - \alpha)S_p k_L| < 1 \)), in order to maximize the learning bandwidth. Monotonic convergence is very important for the delicate hardware, but the necessary use of a Q-filter will limit the learning bandwidth of the repetitive controller. The realizable learning bandwidth strongly depends on the quality of the system identification and the ability of the L-filter to compensate for the resonances within the required learning bandwidth. If for the final hardware fast settling can only be achieved while ignoring the rule of monotonic convergence, the repetitive method will be used to generate a satisfactory FF-signal, after which the learning is switched off. This FF-signal can then be applied to either the MbFF or the hybrid approach.

discussed in Section III-A, which one to choose will depend on the final system configuration.

We tested this scenario in simulation on the non linear MCCD model by first applying the repetitive controller to the plant for a 0 to 8.5 mrad chop sequence. The repetitive method generates an FF signal which we then used as the FF input for both the MbFF and hybrid control strategies. A close up of this simulation at the 8.5 mrad position after 10 seconds of chopping is given in Fig. 15. The different methods show comparable step results, which can be explained by the high accuracy of the FF signal (small positional errors during the step and accurate end position).

V. CONCLUSIONS

We tested the performance of the MCCD applying a new hybrid control strategy and compared the results to those when using a repetitive controller. The hybrid control strategy has been developed to eliminate the typical negative effect of the closed loop controller on settling when tracking fast reference profiles applying the standard MbFF technique. Simulation results presented in Section III-A show that for the considered plant uncertainties, the hybrid method out performance the MbFF technique when fast reference signals are applied.

Detailed system identification revealed the presence of non negligible non linearities in the mechanism. The developed non linear plant model clearly explains the observed non linear behaviour of the plant. Accurate tuning of the non linear system parameters is however difficult, and the approach was considered to be too complex for implementation in the final hardware. This limits the performance of any MbFF approach (including the proposed hybrid controller).

The results of the repetitive controller are very promising. We applied an open loop learning approach to show the possible performance of the repetitive control strategy without the need for \( S_p \) inversion. The repetitive controller can handle the non linearities in the plant. When chopping in the \( \theta_q \) direction we reach the reproducibility limit of the system, which means that we make maximum use of its capabilities.

As the repetitive method is a well established control strategy with a firm mathematical background, and as it has shown its applicability to the hardware, this control strategy will be applied to the final MCC mechanism. If satisfying monotonic convergence limits the settling performance, the repetitive method will be used for learning of the FF-signal offline after which this FF can be applied to the MbFF or hybrid method.

The performed test program concludes the METIS Cold Chopper Demonstrator project. Because of the very promising results when applying the repetitive controller it was decided not to change the MCC design significantly for the final hardware. This means no reduction of hysteresis in the actuators. We believe that detailed tuning of the feedback controller in the final setup, and limiting the amplifier range will suffice to meet the positional stability requirement. Recommendations concerning the allowed resonance spectrum of the mechanical interface of the MCCD with the METIS instrument were provided to the METIS design team.

ACKNOWLEDGMENTS

The authors would like to thank W. Horinga and B. Kramer for their support during the test campaign and J. Evers for valuable input on product and quality assurance.

METIS is a collaboration between NOVA, UK-ATC, CEA Saclay, ETH Zurich, KU Leuven, MPIA and U Vienna. The MCCD project was funded by a generous ESFRI grant from NWO as part of the METIS development program. NOVA was responsible for the project management. The design and realization of the MCC hardware (mechanics and electronics) as well as the breadboard, qualification and lifetime testing were the responsibility of JPE BV. The NOVA - optical/infrared instrumentation group was responsible for the system engineering of the project. TNO provided general consultancy. The controller design and the performance test program of the mechanism was a combined effort of the University of Groningen and SRON.
