Abstract—Code smells are symptoms of poor design and implementation choices that may hinder code comprehension, and possibly increase change- and defect-proneness. A vast catalogue of smells has been defined in the literature, and it includes smells that can be found in any kind of system (e.g., God Classes), regardless of their architecture. On the other hand, software systems adopting specific architectures (e.g., the Model-View-Controller pattern) can be also affected by other types of poor practices. We surveyed and interviewed 53 MVC developers to collect bad practices to avoid while working on Web MVC applications. Then, we followed an open coding procedure on the collected answers to define a catalogue of six Web MVC smells, namely Brain Repository, Fat Repository, Promiscuous Controller, Brain Controller, Laborious Repository Method, and Meddling Service. Then, we ran a study on 100 MVC projects to assess the impact of these smells on code change- and defect-proneness. In addition, we surveyed 21 developers to verify their perception of the defined smells. The achieved results show that the Web MVC smells (i) more often than not, increase change- and defect-proneness of classes, and (ii) are perceived by developers as severe problems.

I. INTRODUCTION

God Classes, Feature Envy, Blob Classes, and Spaghetti Code are examples of well-known code smells, i.e., symptoms of poor design and implementation choices [1], [2]. Evidence in the literature suggests that code smells can hinder code maintainability [3], [4], [5], and increase change- and defect-proneness [6], [7].

While these smells fit well in any object-oriented system, they do not take into account the underlying architecture of the application or the role played by a given class. For example, in web systems relying on the MVC pattern [8], Controllers are classes responsible to control the flow between the view and the model layers. Commonly, these classes represent an endpoint for other classes, do not contain state, and manage the control flow. Besides being possibly affected by “traditional smells” (e.g., God Classes), good programming practices suggest that Controllers should not contain complex business logic and should focus on a limited number of services offered to the other classes. Similarly, Data Access Object (DAO) classes [9] in MVC applications are responsible for dealing with the communication towards the databases. These classes, besides not containing complex and long methods (traditional smells) should also limit the complexity of SQL queries residing in them.

Indeed, traditional code smells capture very general principles of good design. However, we suggest that specific types of code smells, such as the aforementioned ones, are needed to capture “bad practices” on software systems adopting a specific architecture. Hence, the non-existence of a rigorous smells catalogue specific to an architecture (e.g., Web MVC) implies (i) a lack of explicit knowledge to be shared with practitioners about good and bad practices in that architecture, (ii) no available detection tools to alarm developers about the existence of the smell, and (iii) no empirical studies about the impact of these bad practices on code maintainability properties. For these reasons, good and bad practices that are specific to a platform, architecture or technology have been recently emerging as a research topic in software maintenance. In particular, researchers have studied smells specific to the usage of object-relational mapping frameworks [10], Android apps [11], [12], and Cascading Style Sheets (CSS) [13].

In this paper, we provide a catalogue of six smells that are specific to web systems that rely on the MVC pattern. The use of MVC for web development is widely spread and applied by many of the most popular frameworks in the market, such as Ruby on Rails, Spring MVC, and ASP.NET MVC. To produce the catalogue, we surveyed and interviewed 53 different software developers about good and bad practices they follow while developing MVC web applications. Then, we applied an open coding procedure to derive the smell catalogue from their answers. The defined smells are: Brain Repository, Fat Repository, Promiscuous Controller, Brain Controller, Laborious Repository Method, and Meddling Service. We evaluated the impact of the proposed smells on change- and defect-proneness of classes in 100 Spring MVC projects. In addition, we performed a survey with 21 developers to verify whether they perceived classes affected by the defined smells as problematic.

Our findings show that all the proposed smells have a negative impact on class change-proneness. Also, Meddling Services increase class defect-proneness. Finally, developers perceive classes affected by these smells as problematic, at least as much as classes affected by traditional smells.

Specifically, the main contributions of this paper are:

1) A validated catalogue of smells affecting Web applications relying on the MVC pattern. This catalogue has been defined by means of an open coding process after surveying and interviewing 53 software developers.
Detection strategies for each of the catalogued smells

We followed Lanza and Marinescu’s approach [14] to propose detection strategies. These strategies have been implemented in an open source detection tool [15].

An empirical study on the impact of the catalogued smells on change- and defect-promeness of classes. We evaluated the impact of each smell in 100 Spring MVC projects.

A survey on developers’ perception of the smells. We performed a survey with 21 software developers and captured their perceptions on the catalogued smells.

A publicly available replication package [16], reporting all data collected in our studies.

II. THE CATALOGUE OF WEB MVC SMELLS

This section presents the catalogue of Web MVC smells and the details of the method adopted in its definition.

A. Background in MVC Web Development

The MVC pattern [8] has been widely adopted by the web development industry. Frameworks such as Spring MVC (Java), ASP.NET MVC (.NET), Ruby on Rails (Ruby), and Django (Python) have MVC in their core. Thus, developers need to write code for each one of the three layers of the MVC. In this paper, we focus on the server-side code developers are required to write in both控制器 and Model layers.

Controllers, as the MVC pattern states, take care of the flow between the model and the view layers. The Model layer represents the business model. In this layer, developers commonly make use of other patterns [9], [17], such as Entities, Repositories, and Services. Entities represent a domain object (e.g., an Item or a Product). Repositories are responsible to encapsulate persistence logic, similar to Data Access Objects [9]. Finally, Services are implemented when there is a need to offer an operation that stands alone in the model, with no encapsulated state. It is also common to write utility classes, which are commonly called Components; practical examples of them can be UI formatting or data conversion.

As discussed in detail in Section III-B, we evaluated the impact of the catalogued smells in Spring MVC projects, a popular Java framework for web development. Indeed, these different architectural roles can be seen in all the aforementioned frameworks.

B. Smell Discovery Approach

We collected good and bad practices followed by developers while working on Web MVC applications. The data collection included three different steps detailed in the following.

Step 1: Layer-focused survey (S1). We designed a simple survey comprising three sections: Model, View, and Controller. In each section, we asked two questions to the participants:

1) Do you have any good practices to deal with X?
2) Do you have anything you consider a bad practice when dealing with X?

where X was one of the three investigated layers (i.e., Model, View, or Controller).

The goal of this first survey was to shed some light on good and bad practices followed by developers when dealing with code belonging to the three different MVC layers.

We shared the survey in software development discussion lists as well as in personal and industry partners’ Twitter accounts. We collected 22 complete answers.

Step 2: Role-focused survey (S2). We designed a survey aimed at investigating good and bad practices related to code components playing a specific role in the MVC architecture in web applications.

The questionnaire contained five open questions, one for each of the roles mentioned in Section II-A: Controller, Entity, Service, Component, and Repository. We asked participants about good and bad practices they perceive for classes playing each of these roles. In order to recruit participants, we sent invitations to 711 developers who did at least one commit in the previous six months (July-December, 2014) in one of the 120 Spring MVC projects hosted on GitHub. Such a list of projects has been collected using BOA [18], a dataset with structured information about projects in GitHub. We received 14 answers to this survey.

Step 3: Unstructured interviews with industrial developers (S3). We interviewed 17 professional developers from one of our industry partners. All participants worked at the time of the interview on a Java-based Spring MVC web application that has been developed for 11 years, and has more than 1 million lines of code in its main module. The focus of the interview was to make participants discuss about their good and bad practices in each of the five main architectural roles in MVC Web applications. All interviewees were developers or technical leaders. Interviews were conducted by two of the authors, and took 4:30 hours in total. They were fully transcribed.

Overall, we collected information about good and bad practices followed in MVC Web applications from 53 participants. To report some demographic data, our surveys as well as our interviews asked participants about their experience in software and web development. Complete data is shown in Figure 1. Participants were mostly experienced in both software and web development. 46 (83%) had more than 3 years of experience in software development, and 18 (33%) had more than 10 years.

We used the answers provided by participants to our surveys and interviews as the starting point to define our smells catalogue. In particular, two of the authors performed an open coding process on the reported good and bad practices in order to group them into categories. They focused on identifying smells that can be considered as specific of the Web MVC architecture. For example, answers like “large classes should be avoided” were not taken into consideration, since large classes should be avoided in any type of system [1], independently from its architecture. Instead, answers like “a repository method should not have multiple queries” were considered indicative of MVC-specific smells, and thus categorized into a high-level concept, which afterwards became a smell (e.g.,
A Validated Set of Smells in Model-View-Controller Architectures

We define the smell as “Controllers offering too many actions”. To detect them, we rely on the number of routes implemented in the Controller and the number of Services the Controller depends on. The reasoning is that a Controller offers many actions when it provides many different endpoints and/or deals with many different Service classes. Therefore, to detect the smell, we propose the metrics NOR (Number of Routes), which counts the number of different routes a Controller offers, and NSD (Number of Services as Dependencies), which counts the number of dependencies that are Services. In Formula 1, we present the detection strategy, where $\alpha$ and $\beta$ are thresholds.

\[(NOR > \alpha) \lor (NSD > \beta)\] (1)

**Brain Controller.** The most mentioned smell by our participants ($n = 25$) is the existence of complex flow control in Controllers. In Web MVC applications, Entities and Services should contain all business rules of the system and manage complex control flow. Even if a Controller contains just a few routes (i.e., is not a Promiscuous Controller), it can be overly smart. According to S1-P19, this is a common mistake among beginners: “Many beginners in the fever to meet demands quickly, begin to do everything in the controller and virtually kill the Model and the Domain, leaving the system just like VC.” S3-P7 also states that his team does not unit test Controllers, and thus, complex logic and control flow in them should be avoided.

When discussing the smell with the expert, he agreed that the flow control in Controllers should be very simple. Thus, we come up with the following definition for the smell: “Controllers with too much flow control”.

As a proxy to measure the amount of flow control in a Controller, we derived the NFRFC (Non-Framework RFC) from the RFC (Response for a Class) metric that is part of the CK metric suite [19], an oft used suite of object-oriented metrics. The common RFC metric counts the number of all method invocations that happen in a class. However, it also counts invocations to the underlying framework. As confirmed by our expert, Controllers perform several operations on the underlying framework, and these should happen there. Thus, NFRFC ignores invocations to the framework API, which makes the metric value represent the number of invocations that happen to other classes that belong to the system. In Formula 2, we present the detection strategy, where $\alpha$ represents the threshold:

\[(NFRFC > \alpha)\] (2)

**Meddling Service.** Services are meant to contain business rules and/or to control complicated business logic among different domain classes. However, they should not contain SQL queries. While 2 participants mentioned that this is a...
bad practice, all participants in the interview were clear about
where the SQLs should be (good practice): in R
SERVICES may be problematic. S3-P15 stated: “Never get
data [from the database] directly in the Service; Services
should always make use of a Repository.”. Our expert also
confirmed the smell with no further thoughts.

We define this smell as “Services that directly query the
database”. If a SERVICE contains a dependency to any per-
sistence API provided (e.g., JDBC, Hibernate, JPA, iBatis) and
makes use (one or more times) of this dependency, then we
consider this class to be smelly. In Formula 3, we present its
detection strategy for a class C:

\[ \exists \text{persistenceDependency}(C) \]  \hspace{1cm} (3)

**Brain Repository.** Repositories are meant to deal with the
Persistence mechanism, such as databases. To that, they com-
monly make use of querying languages, such as SQL or JPQL
(Java’s JPA Query Language). However, when REPOSITORIES
contain complicated (business) logic or even complex queries,
participants (n = 24) consider that class smelly. S3-P10 states that “When it is too big [the query], ...
if we break it a little, it will be easier to understand.”. S3-P14 strongly states: “No business rules in Repositories. It can search and filter data. But no rules.” Therefore, we define this smell as “Complex
development logic in the repository”.

While discussing the smell with the expert, he mentioned
that two situations are common in real world REPOSITORIES,
and sometimes happen in the same class: (1) very complex
SQL queries, i.e., a single query that joins different tables,
contains complex filters, etc, and (2) complex logic to build
dynamic queries or assembly objects that result from the
execution of the query. According to him, if both these two
types of complexity are in a class, then the class has a
symptom of bad code. Thus, we detect a BRAIN REPOSITORY
by identifying the ones in which the McCabe’s Complexity
Number [20] and the SQL complexity are higher than a
threshold. McCabe’s Number counts the number of different
branch instructions, e.g., if, for, inside of a class. Similarly,
to define the SQL complexity, we counted the occurrence of
the following SQL commands in a query: WHERE, AND, OR,
JOIN, EXISTS, NOT, FROM, XOR, IF, ELSE, CASE, IN. In
Formula 4, we present the detection strategy, where \( \alpha \) and \( \beta \)
are thresholds:

\[ (McCabe > \alpha \land SQLComplexity > \beta) \] \hspace{1cm} (4)

**Laborious Repository Method.** As a good practice, a
method should have only one responsibility and do one thing
[21]. Analogously, if a single method contains more than one
query (or does more than one action with the database), it may
be considered too complex or non-cohesive. Although just one
participant (S1-P1) raised this point, both authors selected the
smell during the analysis, and our expert confirmed that it is
indeed a bad practice, as it reduces the understandability of
that method.

Thus, we define the smell as “a Repository method having
multiple database actions”. The detection strategy relies on the
number of methods that “execute” a command in the
underlying persistence mechanism. We argue this is a good
proxy for the number of actions or executed queries. In
practice, developers need to invoke many different methods
of the API to build the query, pass the parameters, execute,
and deal with its return. Using Java as example, we present a
list of methods (actions) for many different persistence
APIs which should happen only once in each method: For
Spring Data, query(), for Hibernate, createQuery(), createSql-
Query(), createFilter(), createNamedQuery(), createCriteria(),
for JPA, createNamedQuery(), createNativeQuery(), create-
Query(), createNamedQuery(), createNamedQuery(), createStoredProcedure(), getCriteriaBuilder(), and
for JDBC, prepareStatement(), createStatement(), prepare-
Call(). If a method contains two invocations to any of the
methods above, we consider the class as smelly. In Formula 5,
we present the smell’s detection strategy for class C:

\[ \forall \text{m} \in C \exists \text{qtyPersistenceActions}(m) > 1 \] \hspace{1cm} (5)

**Fat Repository.** Commonly, there is a one-to-one relation
between an ENTITY and a REPOSITORY. e.g., the entity Item
is persisted by ITEMREPOSITORY. If a REPOSITORY deals
with many entities at once, this may imply low cohesion and
make maintenance harder. Participants (n = 6) mentioned
that repositories should deal with only a single entity. S3-
P12 stated: “[A problem is to] use more than one Entity in a
Repository. The repository starts to lose its cohesion.”.

Our expert agreed with this smell with no further com-
ments. Therefore, we define it as “a Repository managing
too many entities”. We count the number of dependencies a
REPOSITORY has directly to classes that are ENTITIES. We call
this metric CTE. If this number is higher than the threshold,
the class is considered smelly. In Formula 6, we present the
detection strategy, where \( \alpha \) is the threshold:

\[ (CTE > \alpha) \] \hspace{1cm} (6)

In the following sections, we evaluate the impact of our
catalogue of smells from a quantitative (change- and defect-
proneness of classes) and a qualitative (developers’ perception)
point-of-view.

**III. Smell Evaluation Study Design**

The goal of the study is to investigate whether the defined
catalogue of MVC smells has impact on different maintainabil-
ity aspects of a class, such as its change- and defect-proneness,
and whether developers perceive classes affected by our six
smells as problematic. The quality focus is on source code
quality and maintainability that might be negatively affected
by the presence of the defined smells.

**A. Research Questions**

Our study aims at addressing the following three research
questions:
RQ1. What is the impact of the proposed code smells on change-proneness of classes? Previous studies have shown that the “traditional smells” (e.g., Blob Classes) can increase class change-proneness [6], [7]. This research question aims at investigating the impact of the six Web MVC smells on change-proneness of classes.

RQ2. What is the impact of the proposed code smells on defect-proneness of classes? This research question mirrors RQ1. Traditional smells are also known by their impact on the defect-proneness of classes [6], [7]. Thus, we compare the impact of the six defined smells on defect-proneness of classes.

RQ3. Do developers perceive classes affected by the proposed code smells as problematic? Our last research question qualitatively complements the quantitative analysis performed in the context of RQ1 and RQ2. Here we investigate whether classes affected by the defined Web MVC code smells are perceived as problematic by developers.

B. Context Selection

To answer our research questions, we need to identify instances of the defined code smells in MVC software projects. We select Spring MVC projects from Github as subject systems. We focus our attention on the Spring MVC framework since: (i) it uses stereotypes to explicitly mark classes playing the different roles introduced in Section II-A (e.g., CONTROLLERS), thus making simple identifying the role of each class, and (ii) as shown in a survey conducted with over 2,000 developers [22], it is widely adopted by developers (>40% of the respondents claimed to use it).

We use BOA [18] to select our sample. BOA allows users to query its data using its own domain specific language. We define a query to select Spring MVC projects: (i) having more than 500 commits in their history, and (ii) containing at least 10 CONTROLLERS. Although the constants 500 and 10 are chosen by convenience, we conjecture that they filter out pet projects and small experiments developers host on GitHub. We also manually inspect the sample to make sure they were stand-alone systems. We end up with 120 Spring MVC projects. The complete list is available in our online appendix [16], while Table I reports size attributes of the subject systems.

From the 120 subject projects, 20 are randomly selected, to tune the thresholds of our detection strategies, as described in Section III-D. The remaining 100 are used, as detailed in Section III-C, to answer our research questions.

To answer RQ3, we recruit 21 Spring MVC developers among our industry contacts, asking them to take part in an online survey aimed at assessing their perception of the defined smells. Figure 2 depicts participants’ experience in software development as well as in the development of Spring MVC applications. Participants are generally quite experienced in software development. In particular, 13 of them have more than 8 years of experience. Their level of experience with the Spring MVC framework is spread, varying from 1 to 2 years of experience (10 participants) to more than 8 years (3 participants). None of the developers surveyed in RQ3 had been contacted or involved in the steps performed for the definition of the code smells catalogue.

C. Data Collection and Analysis

To answer RQ1 and RQ2, we need to assess the impact on change- and defect-proneness, respectively, of the defined Web MVC smells. Firstly, it is important to clarify that, while we answer RQ1 by analyzing the complete change history of all 100 subject systems, we only consider a subset of 16 manually selected projects to assess the impact of the MVC smells on defect-proneness (RQ2). These systems are the ones having enough information to compute the classes’ defect-proneness.

Indeed, while to measure the change-proneness of a class C in a time period T it is sufficient to count the number of commits in which C has been modified during T, to assess C’s defect-proneness we need to count the number of bugs found in C during T. This information is typically stored in the issue tracker that, however, was not available for most of the subject systems. Thus, to measure the defect-proneness of C over T, we rely on Fischer et al.’s approach [23]. The approach uses regular expressions to identify fixing-commits as the ones having commit messages containing keywords indicating bug fixing activities, such as bug or fix (i.e., the defect-proneness of C over T is the number of fixing-commits in which C was involved during T). However, to succeed in this measurement, we need software projects having (i) commit messages written in English, and (ii) using words such as “bug” or “fix” in commit messages. We manually analyze the commits of the 100 projects ending up with 16 of them meeting our requirements. These 16 projects are thus exploited in the context of RQ2 and listed in our online appendix [16].

To assess the impact on change- and defect-proneness of the Web MVC smells, we follow an approach similar to what is done in a previous study [6] investigating traditional smells. Firstly, as performed by Kim et al. [24], we split the change history of the subject systems (100 for RQ1 and 16 for RQ2) in chunks of 500 commits, excluding the first chunk likely representing the project’s startup. We indicate the two commits delimiting each chunk as $C_{start}$ (i.e., the 1st commit) and $C_{end}$ (i.e., the 500th commit). We only analyze commits that were merged into the main development branch, i.e., in Git, the master branch.
We obtain 291 chunks for systems used in RQ1 and 77 for those used in RQ2. We run our detection strategies on the $C_{\text{start}}$ of each chunk, obtaining a list of smelly and of clean classes. Then, we compute the change proneness of each class (both smelly and clean classes) as the number of commits impacting it in the 500 commits between $C_{\text{start}}$ and $C_{\text{end}}$. As done by Khohm et al. [6], we mark a class as change-prone if it has been changed at least once in the considered time period. Finally, to have a term of comparison, we also detect six traditional smells in the $C_{\text{start}}$ commit of each chunk. We identify traditional smells by executing PMD 5.4.2 [25], a popular smell detector. We use it to detect instances of six smells, namely God Class, Complex Class, Long Method, Long Parameter List, Coupling Between Objects, and Long Class. Our choice of the traditional smells to consider is not random, but based on the will to consider smells capturing poor practices in different aspects of object-oriented programming, such as complexity and coupling, and previously studied by other researchers [26], [27], [28].

To compare the change-proneness of MVC-smelly, traditional-smelly, and clean classes we compute the following six groups:

- $NC_{\text{Clean}}$, the number of clean classes (not affected by any MVC or traditional smell) that are not change-prone;
- $C_{\text{Clean}}$, the number of clean classes that are change-prone;
- $NC_{\text{MVC-smelly}}$, the number of MVC-smelly classes that are not change-prone;
- $C_{\text{MVC-smelly}}$, the number of MVC-smelly classes that are change-prone;
- $NC_{\text{T-smelly}}$, the number of traditional-smelly classes that are not change-prone;
- $C_{\text{T-smelly}}$, the number of traditional-smelly classes that are change-prone.

Then, we use Fisher’s exact test [29] to test whether the proportions of $C_{\text{MVC-smelly}}/NC_{\text{MVC-smelly}}$ and $C_{\text{Clean}}/NC_{\text{Clean}}$ significantly differ. As a baseline, we also compare the differences between $C_{\text{T-smelly}}/NC_{\text{T-smelly}}$ and $C_{\text{Clean}}/NC_{\text{Clean}}$. In addition, we use the Odds Ratio (OR) [29] of the three proportions as effect size measure. An OR of 1 indicates that the condition or event under study (i.e., the chances of inducing change-proneness) is equally likely in two compared groups (e.g., clean vs MVC-smelly). An OR greater than 1 indicates that the condition or event is more likely in the first group. Vice versa, an OR lower than 1 indicates that the condition or event is more likely in the second group.

We mirror the same analysis for defect-proneness (RQ2). Again, a class is considered to be defect-prone in a chunk if it is involved in at least one fixing-commit during the 500 commits composing the chunk. In this case, the six groups of classes considered to compute the Fisher’s exact test and the OR are $ND_{\text{Clean}}$, $D_{\text{Clean}}$, $ND_{\text{MVC-smelly}}$, $D_{\text{MVC-smelly}}$, $ND_{\text{T-smelly}}$, $D_{\text{T-smelly}}$, where D and ND indicate classes in the different sets being (D) and not being (ND) defect-prone.

Note that, to reduce bias in our analysis, we only consider Controllers, Services, and Repositories in the sets of clean, MVC-smelly, and T-smelly, since our smells focus on these classes. We also made sure to remove classes that were affected by both smells (MVC- and T-smell). In addition, since classes affected by traditional smells or by our defined MVC-smells are expected to be large classes (e.g., a Promiscuous Controller is likely to be a large class), and it is well known that large classes have a higher change- and defect-proneness, we control for the size confounding factor. To this aim, we report the results of our analysis when considering all classes (no control for size) as well as when grouping classes into four groups, on the basis of the size distribution of all classes considered in our study. In this way, we compare the change- and defect-proneness of clean and smelly classes having comparable size.

Finally, concerning RQ3, all 21 participants took part in an online survey composed of two main sections. The first one aimed at collecting basic information on the participants’ background, and in particular on their experience (data previously presented in Figure 2). In the second section, participants were asked to look into the source code of six classes and, for each of them, answer the following questions:

Q1 In your opinion, does this class exhibit any design and/or implementation problem? Possible answers: YES/NO.

Q2 If YES, please explain what are, in your opinion, the problems affecting the class. Open answer.

Q3 If YES, please rate the severity of the design and/or implementation problem by assigning a score. Possible answers on a 5-point Likert scale going from 1 (very low) to 5 (very high).

Q4 In your opinion, does this class need to be refactored? Possible answers: YES/NO.

Q5 If YES, how would you refactor this class? Open answer.

The selected classes are randomly selected for each participant from a set of 90 classes randomly sampled from the 100 subject systems. This set contains 30 classes affected by one of the proposed MVC-smells (five classes per smell type), 30 classes affected by the six traditional smells (five classes per smell type), and 30 non-smelly classes. Note that also in this case we reduce possible bias by only considering
in all three sets classes being **CONTROLLERS**, **SERVICES**, or **REPOSITORIES**, since these are the specific architectural roles on which our smells focus. Each participant evaluated six randomly selected classes, two from each of these three groups, i.e., two MVC-smelly, two T-smelly, two clean classes.

To reduce learning and tiring effects, each participant received the six randomly selected classes in a random order. Also, participants were not aware of which classes belong to which group (i.e., MVC-smelly, traditional-smelly, and clean). They were simply told that the survey studied code quality in MVC web applications. No time limit was imposed for them to complete the task.

To compare the distributions of the severity indicated by participants for the three groups of classes, we use the unpaired Mann-Whitney test [30]. The latter is used to analyse statistical significance of the differences between the severity assigned by participants to problems they spot in MVC-smelly, traditional-smelly, and clean classes. The results are considered statistically significant at $\alpha = 0.05$. We also estimated the magnitude of the measured differences by using Cliff’s Delta (or $d$), a non-parametric effect size measure [31] for ordinal data. We followed well-established guidelines to interpret the effect size values: negligible for $|d| < 0.14$, small for $0.14 \leq |d| < 0.33$, medium for $0.33 \leq |d| < 0.474$, and large for $|d| \geq 0.474$ [31]. Finally, we report qualitative findings derived from the participants’ open answers.

### D. Thresholds Tuning

The detection strategies are based on the combination of different measurements (e.g., code metrics) and use a set of thresholds to spot smelly classes.

In Formula 7, we present the formula used to define the thresholds ($TS$) for each metric. Basically, the formula aims at defining thresholds spotting classes that, for a specific metric, represent outliers. It makes use of the third quartile ($3Q$) and the interquartile range ($3Q - 1Q$) that was extracted from projects that were selected for this tuning. As each smell corresponds to a single specific role, and some metrics are specific to them, i.e., number of routes can only be calculated in **CONTROLLERS**, only classes of that role were taken into account during the analysis of the distribution. The use of quantile analysis is similar to what has been proposed by Lanza and Marinescu [14] in order to define thresholds for their detection strategies.

$$TS = 3Q + 1.5 \times IQR$$

\[(7)\]

In Table II, we present the thresholds derived for each metric ($\alpha$ and $\beta$ in the Formulas presented in Section II-C).

### IV. RESULTS

Table III reports the number of smells identified in the last snapshot of the 100 subject systems. In particular, we report for each of the three architectural roles taken into account by our smells (i.e., **REPOSITORIES**, **CONTROLLERS**, and **SERVICES**) (i) the total number of classes playing this role in the 100 systems (e.g., 1,185 **REPOSITORIES**), (ii) the number and percentage of these classes affected by each smell (e.g., 85 **REPOSITORIES** are **BRAIN REPOSITORY** — 7.1%).

Overall, we identified 1,047 smells in 851 classes out of the 6,436 classes playing one of the three roles described above (16%). The most common smell in terms of percentage of affected classes is the **BRAIN REPOSITORY** (20.5%) followed by the **ROMISCUOUS CONTROLLER** (12.2%) and the **BRAIN CONTROLLER** (7.4%). The least diffused smell is instead the **MEDIATING SERVICE** with only 3.9% of affected **SERVICES**.

We also detected 4,619 traditional smells in 1,580 classes of the same sample (24%). The intersection between the 851 MVC-smelly classes and the 1,580 traditional-smelly classes contains only 388 classes. Also, all the proposed smells identified classes that were not identified by the traditional ones. This indicates that the proposed smells select classes which are not currently identified by any of the traditional smells used in this study.

### Table IV: Odds ratio in change- and defect-proneness between MVC-smelly, traditional-smelly and clean classes.

(CP) Change-proneness, (DP) Defect-proneness,

(*) Fisher’s exact test < 0.05.
A Validated Set of Smells in Model-View-Controller Architectures

A. Impact on Change- and Defect-Proneness

Table IV reports the results of Fisher’s exact test (significant p-value represented by the star symbol) and the OR obtained when comparing the change- and defect-proneness of (i) MVC-smelly classes vs clean classes, (ii) traditional-smelly classes vs clean classes, and (iii) MVC-smelly classes vs traditional-smelly classes. We also report the confidence intervals (at 95% confidence level) in our online appendix [16].

As explained in Section III-C, we report both results when considering in the comparison all classes (no control for size) as well as when grouping classes into groups, on the basis of their size. Note that we do not report the results for small and medium/small classes due to lack of data: classes affected by MVC and traditional smells are for the vast majority at least medium/large classes.

When comparing the change- and defect-proneness of MVC-smelly classes and of clean classes not controlling for size, Fisher’s exact test reports a significant difference, with an OR of 2.97 for change- and 2.05 for defect-proneness. When controlling for size, differences are also significant, but less marked. For change-proneness, we observe an OR of 1.42 in medium/large classes (i.e., 42% higher chance of changing with respect to clean classes), and 1.60 in large classes. In terms of defect-proneness, we do not observe any significant difference when controlling for size.

As a term of comparison, it is interesting to have a look to the results obtained when comparing the change- and defect-proneness of classes affected by traditional smells with clean classes and with classes affected by MVC-smells. Results in Table IV show that:

1) Traditional smells have a strong negative impact on change-proneness. However, as also observed for MVC-smells, they have no impact on defect-proneness when controlling for size. Thus, this only partially confirms previous findings about traditional smells in the literature [6, 7].

2) Traditional smells have a stronger negative impact on change- and defect-proneness as compared to MVC-smells. This also holds for large classes when controlling for size.

To have a closer look into the data, Table V reports the impact on change- and defect-proneness of each of the six MVC-smells presented in this paper. It is important to note that in some cases (e.g., Brain Controller for medium/large classes), it was not possible to perform the statistical test due to lack of data (i.e., very few Brain Controllers are medium/large classes). These cases are indicated with “−” in Table V. The main findings drawn from the observation of Table V are:

1) When obtaining statistically significant difference (* cells in Table V), classes affected by smells have always a higher chance (OR > 1.00) of changing as well as of being subject to bug-fixing activities. This holds both when controlling for size as well as when considering all classes. We cannot claim anything for non-statistically significant results.

2) Brain Repository and Meddling Service are the smells having the strongest impact on change-proneness with an OR close to 3 in large classes (i.e., classes affected by these smells have almost three times more chances to change as compared to clean classes).

3) The Meddling Service smell is the only one having a significant impact on defect-proneness when controlling for size (OR=2.53 in large classes, i.e., classes affected by this smell have over twice more chances of being subject to bug-fixing activities as compared to clean classes).

The defined web MVC smells have a negative impact on class change-proneness (RQ1). In terms of defect-proneness, we claim a negative impact for only for the Meddling Service smell (RQ2).

B. Developers Perception of the Web MVC Smells

In Figure 3a, we present violin plots of the developers’ perception of MVC smells, traditional smells, and clean classes. Also, we report the developers’ perception of each single MVC-smell — Figure 3b — as well as of each considered traditional smell — Figure 3c. On the y-axis, 0 (zero) indicates classes not perceived by the developers as problematic (i.e., answer “no” to the question: Does this class exhibit any design and/or implementation problem?), while values from 1 to 5 indicates the severity level for the problem perceived by the developer.

Clean classes have a median of severity equal to 0 (Q3=2). This indicates that, as expected, developers do not consider these classes as problematic. As a comparison, classes affected by MVC-smells have median=4 (Q3=4.25) and thus, are perceived as serious problems by developers. The difference in developers’ perception between MVC-smelly and clean classes is statistically significant (p-value<0.001) with a large
effect size ($d = 0.56$). Concerning the traditional smells, the severity median is 3 (Q3=4). It shows that classes affected by these smells are perceived by developers as problematic, even if less than MVC-smells. However, while this difference in perception is clear by looking at the violin plots in Figure 3a, such a difference is not statistically significant (p-value=0.21). We conjecture that this might be due to the limited number of data points (21 participants).

God Classes (GC) are the most perceived traditional smell (median=4). Regarding the proposed smells, MEDDLING SERVICE, FAT REPOSITORY, and BRAIN CONTROLLER achieve medians equal to 4, meaning they are perceived as really problematic by the participants. Several developers, without knowing our smells’ catalogue, were able to correctly identify the smell, providing a description very close to the definition of our smells. For instance, one of them when facing a BRAIN CONTROLLER stated: “Property validation and entity construction are really responsibilities that should be encapsulated within the service layer; a lot of domain model knowledge is needlessly leaked into the Controller.”. Another participant simply claimed: “it does too much for a Controller”. Also when facing a PROMISCUOUS CONTROLLER, developers were able to catch the problem (e.g., “I count 12 @RequestMapping!”). The annotation @RequestMapping is indeed used to define a route in a Spring MVC Controller. This maps directly to the concept of our smell. Participants also noticed that BRAIN REPOSITORIES are complex: “programmer(s) should worry just about querying instead of handling and logging hibernate errors”.

The least perceived smells by developers are LABORIOUS REPOSITORY METHOD (MVC) and COMPLEX CLASSES (traditional), as both medians are zero, i.e., over half of the participants did not perceive classes affected by this smell as problematic.

**V. RELATED WORK**

Code smells have been discussed for a while in the software engineering community. Webster’s book [32] may be the first one in which the term code smells was used to refer to bad practices. Long methods and excessive complexity are examples. Since then, many other researchers and practitioners have defined catalogues of code smells. As example, Riel [33] has defined more than 60 different characteristics of good object-oriented code, and Fowler [1] suggests refactoring in more than 20 different code issues. Smells such as God Classes, Feature Envy, and Blob Classes are popular among practitioners and popular tools in industry, such as PMD and Sonar, attempt to detect them.

Researchers evaluated the impact of these smells in terms of code quality. As a first step to identify smelly classes, Marinescu [34] proposed detection strategies that rely on the combination of metric-based rules and logical operators, such as AND or OR. Then, Lanza and Marinescu [14] defined a set of thresholds based on benchmarking metrics in real software systems. In their approach, authors relied on quartile analysis. There exist other approaches in literature, such as HIST [35], which makes use of the evolution history to detect the smells, and DECOR [36], a DSL for specifying smells using high-level abstractions.

After, Khohm et al. [6] showed that smelly classes are more prone to change and to defects than other classes. Li and Shatnawi [37] also empirically evaluated the effects of code smells and showed a high correlation between defect-prone and some bad smells. Yamashita and Moonen [4] showed that the existence of more than a single smell in a class can negatively impact the maintenance of that piece of code. This was also confirmed by Abbes et al. [38], who conducted controlled experiments investigating the impact of some code smells on program comprehension. They showed that the existence of a single smell in a class does not significantly decrease the performance of a developer. However, when a class presented more than one smell, the performance of developers during maintenance tasks was significantly reduced.

Indeed, the perception of a developer may be not precise. A study from Palomba et al. [28] showed that smells related to

---

Class affected by the proposed MVC smells are perceived as problematic by developers when compared to non-smelly classes (RQ3).
A Validated Set of Smells in Model-View-Controller Architectures

A to complex or long source code are perceived as harmful by developers; other types of smells are only perceived when their intensity is high. Yamashita and Moonen [39] conducted a survey with 85 professionals, and results indicate that 32% of developers do not know or have limited knowledge about code smells. Arcanerode et al. [40] performed a survey to understand how developers react to the presence of code smells. The results show that developers postpone the removal to avoid API modifications. Peters and Zaidman [27] analyzed the behavior of developers regarding the life cycle of code smells and results show that, even when developers are aware of the presence of the smell, they do not refactor.

Regarding web development, most studies focus on related client-side technologies, such as bad practices in CSS [41], [42], Javascript [43], [44], and HTML [45]. To the best of our knowledge, no research was focused on code smells for server-side MVC web applications. The smells we propose in this study are currently not captured by “traditional smells”, as the former aim to more general good practices, i.e., they do not focus on SQL complexity (as BRAIN REPOSITORIES do) or number of dependencies to entity classes (as FAT REPOSITORIES do). To perform this research, we relied on current findings and approaches of the field, such as the definition of metric-based code smells detection strategies [14], analysis of the impact on class change- and defect-proneness [6], [7], as well as on developers’ perceptions [28]. As a derived product of this research, we developed an open source tool [15] that reports any class that contains a smell from our catalogue.

VI. Threats to Validity

Threats to construct validity concern the relation between the theory and the observation, and in this work are mainly due to the measurements we performed. Since the subject systems did not have an issue tracker, we relied on the heuristic proposed by Fischer et al. [23] to identify bug fixing commits. We are aware that such a heuristic can introduce imprecisions in the computation of the classes’ defect-proneness. To diminish the issue, we made sure via manual analysis that the systems used in this study use meaningful commit messages.

Detection strategies for the defined smells were derived from the participants’ answers and the expert analysis. There might be better strategies for their detection. Further research needs to be conducted in order to optimize them. However, our current strategies were able to detect classes perceived as problematic by developers and possibly increasing change-proneness. Also, possible imprecisions might be introduced due to errors in the implementation of the tool we wrote to detect the smells. We wrote automated tests to ensure the correct behavior of our tool that is open source.

To determine the thresholds we used in our detection strategies, we applied quartile analysis on a set of projects that were not used to answer our research questions. While other strategies can be used (e.g., Alves et al.’s [46] and Oliveira et al.’s [47]), up to now there is no empirical evaluation of which strategy works best.

Threats to internal validity concern external factors we did not consider that could affect the variables and the relations being investigated. We did not consider possible tangled changes [48] and thus we cannot exclude that some bug fixing commits grouped together tangled code changes, of which just a subset aimed at fixing the bug.

Threats to conclusion validity concern the relation between the treatment and the outcome. Although this is mainly an observational study, wherever possible we used an appropriate support of statistical procedures, integrated with effect size measures that, besides the significance of the differences found, highlight the magnitude of such differences.

Threats to external validity concern the generalisation of results: (1) Although we derived the thresholds to identify the smells on 20 systems, we do not claim these thresholds are the optimal ones. A larger set of systems is needed to increase the thresholds’ generalizability; (2) We evaluated our smells in Spring MVC applications. Although there might be similarities between most of the MVC frameworks, we do not claim that our results are generalizable to all of them; (3) The response rate of our role-focused survey was low. Still, we do not use the answers to generalize the provided catalogue of smells; (4) Finally, our catalogue only includes six smells for MVC web applications. We do not claim this is a comprehensive catalogue. Further research is needed to investigate other possible bad practices in MVC applications.

VII. Conclusions and Future Work

Good practices and code smells are a great asset for developers to increase the quality (and the maintainability) of their software systems. However, most code smell catalogues are focused on general good practices, i.e., practices that can be applied to any system, regardless of its architecture.

In this study, we provide a catalogue of 6 smells that are specific to Web MVC systems, namely BRAIN REPOSITORY, FAT REPOSITORY, PROMISCUCOUS CONTROLLER, BRAIN CONTROLLER, LABORIOUS REPOSITORY METHOD, and MDDLING SERVICE. This catalogue was coined after interviewing and surveying 53 software developers. We also analyzed 100 Spring MVC projects in order to quantify the impact of the proposed smells. We showed that these smells can have a negative impact on class change-proneness and, in the case of MDDLING SERVICE, also on defect-proneness. We also performed a survey with 21 developers about their perceptions on classes affected by these smells, and results show that they perceived smelly classes as highly problematic.

We learned that besides traditional smells, architecture-specific smells can also be problematic for the maintenance of software systems. Web developers can already start to benefit from our catalogue and from the publicly available detection tool [15]. Indeed, a deeper investigation is needed to carefully assess the comprehensiveness of our catalogue as well as the impact of these smells on maintainability (e.g., by running a controlled experiment). This is part of our future work agenda, together with the definition and empirical analysis of other catalogue of smells, specific for other architectures.
