ABSTRACT
A popular form of software reuse is the use of open source software libraries hosted on centralized code repositories, such as Maven or npm. Developers only need to declare dependencies to external libraries, and automated tools make them available to the workspace of the project. Recent incidents, such as the Equifax data breach and the leftpad package removal, demonstrate the difficulty in assessing the severity, impact and spread of bugs in dependency networks. While dependency checkers are being adapted as a counter measure, they only provide indicative information. To remedy this situation, we propose a fine-grained dependency network that goes beyond packages and into call graphs. The result is a versioned ecosystem-level call graph. In this paper, we outline the process to construct the proposed graph and present a preliminary evaluation of a security issue from a core package to an affected client application.

1 INTRODUCTION
Software engineers reuse code to reduce development and maintenance costs. A popular form of software reuse is the use of open-source software (OSS) libraries, hosted on centralized code repositories, such as Maven or npm. In such settings, developers specify dependencies to external library versions in a textual file, that is then committed to the repository of the client program. Automated programs, typically CI systems, resolve the dependency descriptions and connect to the central repositories to download the specific library versions that are required to build the client program. Library names and versions often follow de-facto conventions, such as semantic versioning.

Several implications may arise from the fact that programs and libraries can have dependencies on other libraries, and that dependencies are not resolved in a well-defined manner. Increasingly, libraries are being used as building blocks for creating other libraries, leading to highly interconnected ecosystems [4, 7]. The interconnections form a graph, in which the nodes are versioned libraries and the edges are dependencies on the libraries. The structural properties of those graphs can significantly affect the functionality of thousands of end-user projects [6]. Moreover, including arbitrary code from an online repository induces trust and security implications; how can developers ensure that the imported code contains no security holes? How can they know when a security issue discovered in a transitive dependency requires an update?

Dependency networks also present challenges to library maintainers: how can they assess the direct or transitive impact of their changes?

In the recent years, we have witnessed dependency network failures with severe implications on client programs:

• A dispute over a library name in the npm ecosystem led to the removal of a library called leftpad. The package removal further lead to the collapse of thousands of libraries which directly depended on leftpad, and hence a major disruption for client programs. After the leftpad incident, a study [6] estimated that there exist libraries whose removal can affect more that 30% of the core components of the network.

• A company named Equifax leaked over 100,000 credit card records due to a dependency that was not updated. The compromised systems included a vulnerable version of the Apache Struts library, whose update was postponed as the Equifax security team erroneously underestimated the impact of the bug on their codebase.

• Malicious developers uploaded to the Python package manager (PyPI) libraries whose name was deliberately misspelled, being almost identical to the original libraries (e.g., ur11b instead of urllib3). The intention was to steal information from client applications of developers who had accidentally mistyped the library name in the dependency file.

Recent research has been focused on the analysis of the evolution of code repositories and how libraries are growing together in a shared environment [3, 4, 7]. To study ecosystems, developers typically build dependency graphs, in which nodes represent either libraries or library versions. To represent a dependency (i.e. creating an edge), researchers emulate the version resolution algorithm of the original package manager. While this model is useful for initial evaluations of dependency networks, it can only provide partial information due to the following limitations:

1. The dependency relationship in the network is on a version-basis (e.g library A v1.2.3 depends on library B v2.3.4). Reasoning about how a library can influence other connected libraries on a
version-basis such as bug propagation is limited. (2) A dependency on a library does not necessarily mean that the code in that library is actually used. Providing developers with actionable information such as security alerts on dependencies requires further analysis of dependency relationships. (3) Dependency networks do not enable developers (or researchers) to perform change impact analysis beyond a single library; this leads to lost opportunities of evaluating problems at the ecosystem level.

In our work, we propose to extend dependency networks with call graph information, within and across dependencies, thereby constructing ecosystem-wide dependency network call graphs. This takes into account how libraries are interconnected at the source code level.

Our vision is the following: (1) Construct a dependency network at the function-level granularity. (2) Evaluate the dynamics of changes made to libraries in a dependency network from a program analysis perspective. (3) Study and evaluate historical changes in a dependency network.

In the following sections, we outline concepts of our call graph based dependency network and highlight how it can enable a fine-grained impact analysis assessment.

2 CALL GRAPH BASED DEPENDENCY NETWORK

Most package managers for OSS libraries use a variation of semantic versioning to specify dependency versions. Semantic versioning allows developers to specify dependencies, not only as an exact version but also a version range. The resolution of version ranges to exact versions is time-dependent; the package manager resolves the latest version available at the package repository at the time the resolution was initiated. This complicates precise retrospective studies of dependency networks and makes their results fragile. As an example, consider a library $A$, with two versions: v1.2 released in Oct 2014 and v1.3 released in Oct 2016. A library $B$ depends on version 1.* of library $A$. If we create the dependency graph of the package ecosystem today, we would only resolve the dependency to $A$ v1.3, missing two years worth of time where the correct dependency would be $A$ v1.2.

Consequently, we need a fine-grained dependency network. For this, we can exploit the fact that the vast majority of open source libraries included in dependency networks are developed on GitHub. Instead of relying on aggregated metadata from package managers, such as the data provided by the libraries.io service, we can analyze the commits on the dependency specification files. Using these files, we can construct dependency networks with more details. Following the example above, if the repository exporting library $B$ has received a commit $c$ at any time between Oct 2014 and Oct 2016, then we could resolve $A$ to v1.2 for the version created in $c$. Moreover, relying on GitHub for constructing dependency networks will enable us to include client programs in our analysis, thereby extending the impact of our envisioned analyses.

After obtaining high resolution dependency networks, we need to construct call graphs for each library version that we include in our graph. Creating call graphs can be done either with static analysis, where possible executions are determined from analyzing the source code or through dynamic analysis, where probes are the method invocations recorded at runtime. Our only requirement is that the call graph construction will be able to (statically) construct call graphs that extend beyond a single project to the transitive set of dependencies the project specifies. This requirement is akin to the linking process in compiled languages, and is already supported by many tools.

Next, we need to map the call graph on the dependency network. There are two ways to do this: i) include the generated call graph as an attribute to a dependency network node, or ii) decorate the call graph nodes with metadata about the dependency (e.g., the dependency name and version). We choose the second option, as the graph nodes are functions and represents our end goal of being able to perform impact analysis at an ecosystem level.

By following the steps above, we arrive to the definition of our dependency network call graph as follows:

**Definition.** A dependency network call graph for an ecosystem is a directed and immutable graph $G = (V, C)$ where:

1. $V$ is a set of versioned functions. Each $v \in V$ is a 3-tuple $< id, v, c >$, where $id$ is a fully qualified function name, $v$ is the version of the library and $c$ is the commit.
2. $C$ is a set of edges that connects functions. Each $(v_1, v_2) \in C$ represents a function call from $v_1$ to $v_2$.

Although the dependency network shares some similarities with the work of Hejderup and Kikas et al [5, 6], it differs in that the network is a large interconnected call graph and the versioning is annotated at the function call level. Figure 1 illustrates a simple call graph based dependency network where dependency 1 depends on dependency 2. Inside each dependency block, the nodes represent versioned functions with full function identifier, version and commit revision. The edges in the network can be classified into internal and external calls. An external call is made from the a() node in dependency 1 to the c() node in dependency 2. The process to decide and resolve an external function call into the correct versioned one is not trivial and is explained in the following subsection.

2.1 Network Construction

The process of constructing the network is shown in Algorithm 1. The initial step is to select commits that include changes to the dependency file of the repository (line 3). A change can be a new release of the library or a change to the list of specified dependencies.
For each of the selected commits, the source code of the library is checked-out when the commit was made and a call graph is constructed from the source code (lines 6-7). The functions (i.e., nodes) of the call graph are annotated with information about the commit, name and version of the library and then added to the dependency network (line 8). Depending on the type of the change in the processed commit, there are two sub-cases:

1. If the change is a new release of the library, a copy of the edges representing function calls to external libraries in the previous version is added to the graph.
2. If the change specifies a new dependency, the dependencies need to be re-evaluated and edges from each function in $C_{G_{\text{ann}}}$ to functions in external libraries need to be created.

The process to resolve dependencies is presented in Algorithm 2. The dependency file is obtained and parsed from the commit (lines 3-4). For each dependency, the existing dependency network is sliced by the dependency name, then sliced further by the version that is resolved by emulating the resolution process in the original package manager. The remaining step is to slice at the commit level. The time stamp of the provided commit is extracted and the closest commit to the time stamp in $G_{\text{ver}}$ is selected. The (transitive) call graph for the processed dependency is created and links between the processed dependency and external dependencies are resolved and returned (line 11). After the edges are created, the process repeats until there are no more dependencies to add in the graph.

### 2.2 Impact Analysis

Impact analysis helps in the determination of the subset of the dependency network that is affected by a given set of changes or bugs. The identified subset allows developers and library maintainers to evaluate the impact within or across dependencies at the function call level. As an example, library maintainers can assess the potential impact of a set of changes in the network before releasing a new version. Further, developers can localize functions or methods in the program that are implicitly affected by a critical bug in a transitive dependency. Finally, the commit revision in the set of 

### 3 INITIAL EVALUATION

The concepts presented in the previous section are implemented in an early prototype in JavaScript and currently process npm-based projects. The dependency resolution mechanism in the prototype is based on npm's semver\(^4\) library, and call graphs are extracted

---

\(^4\)https://github.com/npm/node-semver
from executing test cases of npm packages in Jalangi,\textsuperscript{5} which is a dynamic analysis framework.

The initial evaluation concentrates on testing the concepts in a small controlled setting before attempting processing at an ecosystem-scale. The first use case evaluates the impact of a security bug in the npm ecosystem. Towards this end, we use security advisories from the Node Security Platform and evaluate the impact of a bug discovered in the isaacs/Minimatch library.\textsuperscript{6} The bug is localized in the parse function and we obtained the affected commits tagged with a version (e.g. all <=3.0.1) from the repository. Using reversed dependency resolution in place of a call graph network in Algorithm 3, led to the discovery of over 36,000 npm packages that directly or indirectly resolve to a vulnerable version of Minimatch; our results are publicly available.\textsuperscript{7}

We selected an arbitrary package called globwatch (v0.0.1) from the results and checked-out the commit 82cef59 from airportyh/globwatch\textsuperscript{8}. This npm module continuously keeps watching for file changes via a user-defined glob pattern. We obtained the call graph by executing the test cases in Jalangi and later traversed the call graph to find call-paths that implicitly use the parse function in isaacs/Minimatch (v0.2.14/72845fa). The impacted set resulted in two distinct call-paths, of which, the output of one call path is presented in Figure 2 where the call is executed from top to bottom. Each node in the figure contains the commit sha and also the line and the column information of the function in the source code. The line and column number information is retained to precisely identify anonymous function (e.g anonFn) bodies in JavaScript.

\section{4 DISCUSSION & CHALLENGES}

The sheer size of code repositories and the frequent release of libraries poses many challenges to the construction and maintenance of a versioned call graph based dependency network. The concepts presented in Section 2 imply a use of program analysis techniques to construct, infer and traverse call graphs. Performing such an analysis at ecosystem-scale introduces several problems: (1) Obtaining a sound or accurate call graph can be computationally expensive, thus making the construction of the network time consuming. (2) Having an imprecise call graph could potentially lead to false negatives in the impact analysis. (3) The use of commit time for resolving version ranges in Algorithm 2 could be unreliable for repositories with

\section{5 RELATED WORK}

In several studies [3–7], dependency networks have been used to study the dynamics of interconnected libraries in software ecosystems. However, there is a lack of research on dependency management, and yet, it is among some of the most common activities a developer needs to handle. To the best of our knowledge, there is one qualitative study by Bogart et al [2] that reasons about the cost of changes between library maintainers and their clients. However, none of these studies focus on techniques for a fine-grained and actionable dependency management for developers and library maintainers.

\section{6 SUMMARY}

In this paper, we present a technique to construct and analyze dependency relationships in a software ecosystem at the function-level granularity. The technique combines historical dependency data from version-controlled repositories with call graph construction to build a fine-grained representation of a dependency network. This representation can extend program analysis to diagnose problems at an ecosystem level, such as the spread of a security bug to affected clients or libraries by inspecting their interconnected function call relationship. We believe that our approach points towards actionable dependency management, where dependencies and their changes are evaluated at the source code level.
