Nicotinamide adenine dinucleotide (NAD\(^{+}\)) is a key redox compound in all living cells responsible for energy transduction, genomic integrity, life-span extension, and neuromodulation. Here, we report a new function of NAD\(^{+}\) as a molecular photocatalyst in addition to the biological roles. Our spectroscopic and electrochemical analyses reveal light absorption and electronic properties of two \(\pi\)-conjugated systems of NAD\(^{+}\). Furthermore, NAD\(^{+}\) exhibits a robust photostability under UV-Vis-NIR irradiation. We demonstrate photocatalytic redox reactions driven by NAD\(^{+}\), such as \(\text{O}_2\) reduction, \(\text{H}_2\text{O}\) oxidation, and the formation of metallic nanoparticles. Beyond the traditional role of NAD\(^{+}\) as a cofactor in redox biocatalysis, NAD\(^{+}\) executes direct photoactivation of oxidoreductases through the reduction of enzyme prosthetic groups. Consequently, the synergistic integration of biocatalysis and photocatalysis using NAD\(^{+}\) enables solar-to-chemical conversion with the highest-ever-recorded turnover frequency and total turnover number of 1263.4 hour\(^{-1}\) and 1692.3, respectively, for light-driven biocatalytic trans-hydrogenation.

**INTRODUCTION**

Nicotinamide adenine dinucleotide (NAD\(^{+}\)) is a vital cofactor that functions as an electron carrier in cellular energy transduction (1). The cytosolic and mitochondrial pools of NAD\(^{+}\) modulate the activity of compartment-specific metabolic pathways, such as glycolysis in the cytoplasm and tricarboxylic acid cycle in the mitochondria. In the cytoplasm, NAD\(^{+}\) is reduced to NADH through glycolysis by glyceraldehyde-3-phosphate dehydrogenase. The cytosolic NADH is transported into mitochondria and then oxidized by complex I (NADH:ubiquinone oxidoreductase) for transferring electrons to the electron transport chain. This electron relay drives the chemiosmotic synthesis of adenosine triphosphate as an energy storage molecule. Beyond the role for redox shuttling, NAD\(^{+}\) is a cosubstrate for a variety of redox enzymes, such as poly(adenosine diphosphate (ADP)-ribose) polymerases (PARPs) and sirtuins (SIRTs) (2, 3). Some members of the PARP and SIRT families cleave NAD\(^{+}\) to use the ADP-ribose moiety in the interest of genomic integrity, mitochondrial biogenesis, improved metabolic efficiency, and life-span extension. In addition to intracellular roles, NAD\(^{+}\) functions as a neurotransmitter and neuromodulator in the peripheral nervous system after it is secreted from neurons in blood vessels, the urinary bladder, and the colon (4). For instance, extracellular NAD\(^{+}\) tunes the release of other neurotransmitters (e.g., norepinephrine) in blood vessels, inhibits spontaneous smooth muscle contractions in urinary bladders, and causes membrane hyperpolarization and relaxation in colons.

Here, we report a newly found function of NAD\(^{+}\) as a molecular photocatalyst, distinct from the biological roles of NAD\(^{+}\) as a cofactor, cosubstrate, neurotransmitter, and neuromodulator (Fig. 1). A photocatalyst absorbs light, excites its electrons (or holes) to higher energy levels, and makes the excited charges participate in a photo-redox reaction. Solar energy has emerged as a clean and inexhaustible resource; thus, molecular photocatalysts have been widely applied for solar-driven redox chemistry [e.g., organic synthesis (5), hydrogen production (6), and \(\text{CO}_2\) reduction (6)]. Furthermore, photocatalysis has been recently combined with biocatalysis to expand the scope of cascade-type syntheses (7). NAD\(^{+}\) contains \(\pi\)-conjugated systems (i.e., nicotinamide and adenine), at which electrons are delocalized in circular \(\pi\) bonds from the overlap of hybridized atomic \(p\) orbitals. Upon photosensitization of NAD\(^{+}\), these electrons can be excited to energetically higher levels, obtaining a reducing power enough to reduce adjacent molecules or ions. We have conducted proof-of-concept experiments to demonstrate that NAD\(^{+}\) can perform photocatalytic redox reactions, such as \(\text{H}_2\text{O}\) oxidation coupled with \(\text{O}_2\) reduction and the growth of silver nanoparticles (AgNPs) from Ag\(^{+}\) ion reduction. Furthermore, beyond the function of NAD\(^{+}\) as a cofactor, photoactivated NAD\(^{+}\) can directly activate redox enzymes such as ene-reductases [from the Old Yellow Enzyme (OYE) family] through the electron transfer from NAD\(^{+}\) to the prosthetic flavin moiety. Subsequently, the redox enzyme catalyzes the stereoselective hydrogenation of activated C=C bonds.

**RESULTS**

Electronic property and photostability of NAD\(^{+}\)

To comprehend the origin of NAD\(^{+}\)’s photocatalytic activity, we investigated its electronic properties using ultraviolet-visible (UV-Vis) spectroscopy. NAD\(^{+}\) exhibited a characteristic absorption peak at around 260 nm that stems from the \(\pi\)-\(\pi^*\) electronic transition (8) of nicotinamide and adenine (fig. S1A). Upon shining light (\(\lambda\), \(\approx\)260 nm) on NAD\(^{+}\), \(\pi\) electrons in the nicotinamide and adenine moieties were excited to the lowest unoccupied molecular orbitals (LUMO) or higher energy levels, making NAD\(^{+}\) a potent reductant. Next, we obtained cyclic voltammograms of NAD\(^{+}\) and ferrocene to estimate the energy levels of LUMO and the highest occupied molecular orbital (HOMO) of NAD\(^{+}\). As displayed in fig. S1 (B to D), NAD\(^{+}\) exhibited an onset of reduction wave at around \(-0.94\) V (versus Ag/AgCl) and that of oxidation wave at around 1.20 V (versus Ag/AgCl); the cathodic and anodic currents originated from the reduction of nicotinamide (9) and the oxidation of adenine (10), respectively. On the basis of the formal potential of ferrocene (fig. S1E) and the onset potentials of NAD\(^{+}\), we found that the energies of LUMO\(_{\text{Nicotinamide}}\) and HOMO\(_{\text{Adenine}}\) are \(-0.90\) and 1.24 V (versus Ag/AgCl), respectively. In addition, HOMO\(_{\text{Nicotinamide}}\) of 3.23 V (versus Ag/AgCl) and LUMO\(_{\text{Adenine}}\) of \(-2.89\) V (versus Ag/AgCl) were estimated on the basis of the HOMO-LUMO gap of 4.13 eV (300 nm) from the absorption onset
wavelength (fig. S1F). We verified a negligible photodegradation of NAD+ under illumination (λ, 260 to 900 nm; P_{260–900 nm}, 200 mW cm^{-2}; P_{260–300 nm}, 10 mW cm^{-2}), as shown in fig. S2. This excellent photostability is a highly desirable property of molecular photocatalysts because of photobleaching and instability issues of many molecular photocatalysts (7, 11).

**NAD+**-driven photocatalytic **H₂O** oxidation and **O₂** reduction

Building on the electronic properties and photostability of NAD+, we investigated its capability to photocatalytically reduce O₂ to superoxide ion (O₂^{−}) because its reduction potential (O₂/O₂^{−}, E_{red} = −0.54 V versus Ag/AgCl) (12) is more positive than LUMO_{Nicotinamide} of −0.90 V (versus Ag/AgCl) and LUMO_{Adenine} of −2.89 V (versus Ag/AgCl). We analyzed the formation of superoxide ion (O₂^{−}) using a nitro blue tetrazolium (NBT) assay; the reduction of NBT by O₂^{−} forms NBT formazan, which can be monitored spectrophotometrically at 560 nm (13). As shown in Fig. 2A and fig. S3A, O₂^{−} formation was achieved only under irradiation with light (λ, 260 to 900 nm), and the ion’s concentration increased with the increasing concentration of NAD+ and light intensity (P, 0 to 200 mW cm^{-2}). The photochemical formation of O₂^{−} was also triggered under filtered illumination (λ, 260 to 390 nm; P, 0 to 20 mW cm^{-2}) but not under visible–near-infrared (Vis-NIR) illumination (λ, 360 to 900 nm; P, 0 to 200 mW cm^{-2}). It is ascribed to the negligible photoactivation of NAD+ because NAD+ does not absorb light longer than 300 nm. Control experiments in the absence of NAD+ or O₂ resulted in a background signal (Fig. 2B); NBT, phosphate ions, and UV light were necessities for reduction of NBT to NBT formazan (fig. S3B). According to the literature (14), the exposure of NBT to UV light increases the redox potential of NBT, transforming it into a stronger oxidant to extract electrons directly from neighboring molecules other than from O₂^{−}.

In the photochemical reduction of O₂, an anodic reaction should occur as a counterpart to accomplish a redox reaction. Because we did not use an artificial electron donor for the NAD+-sensitized formation of O₂^{−}, we hypothesized that photoactivated NAD+ can oxidize H₂O. The products of H₂O oxidation with corresponding oxidation potentials at pH 7.5 are as follows (Eqs. 1 to 3) (15)

\[
\begin{align*}
H₂O & \rightarrow OH^{−} + (H^{+} + e^{−}), E_{ox} = 1.73V \text{ (versus Ag/AgCl)} \quad (1) \\
2H₂O & \rightarrow H₂O₂ + 2(H^{+} + e^{−}), E_{ox} = 1.11V \text{ (versus Ag/AgCl)} \quad (2) \\
2H₂O & \rightarrow O₂ + 4(H^{+} + e^{−}), E_{ox} = 0.58V \text{ (versus Ag/AgCl)} \quad (3)
\end{align*}
\]

We measured hydroxyl radicals (OH^{•}) because the one-electron–one-proton oxidation of water (Eq. 1) is kinetically more favorable than two-electron–two-proton or four-electron–four-proton oxidation of water (Eqs. 2 and 3). To determine the concentration of OH^{•}, we...
Fig. 2. NAD⁺-sensitized reduction of O₂ and oxidation of H₂O. (A) Absorbance changes of NBT solution at 560 nm with varying concentration of NAD⁺. ∆A(t) = A(t) − A(t = 0 min). The background signal (displayed in (B)) was not subtracted from ∆A(t). Reaction condition: NAD⁺ and NBT in an O₂-purged sodium phosphate buffer (50 mM, pH 7.5) under irradiation (xenon lamp: λ, 260 to 900 nm and P, 200 mW cm⁻²). (B) A series of control experiments for each reaction component (i.e., 400 μM NAD⁺, light, and O₂) in the photochemical formation of O₂⁻: ∆A = A (30 min) − A (0 min). Reaction conditions: NAD⁺ and NBT in an O₂-purged sodium phosphate buffer (50 mM, pH 7.5) under irradiation (xenon lamp: λ, 260 to 900 nm and P, 200 mW cm⁻²). (C) Effect of NAD⁺ concentration on OH⁻ formation for 30-min irradiation (200 mW cm⁻²). (D) Dependency of OH⁻ formation on the light intensity (t = 30 min). Reaction conditions: 1 mM NAD⁺ and Tris in an O₂-purged sodium phosphate buffer (50 mM, pH 7.5). All reported values represent means ± SD (n = 3).

performed a colorimetric assay using tris(hydroxymethyl)aminomethane (Tris) and Nash’s reagent (12, 16, 17); Tris reacts with OH⁻ to yield formaldehyde (stoichiometric ratio of 1:1:1), and the formaldehyde can be quantitatively monitored using Nash’s reagent (fig. S4). We confirmed that both NAD⁺ and light were requisites for photochemical formation of OH⁻ (fig. S5A); NAD⁺ concentration and light intensity increased the concentration of the radical (fig. 2, C and D). However, the filtered light (λ, 360 to 900 nm; P, 200 mW cm⁻²) did not prompt the NAD⁺-driven generation of OH⁻ due to the negligible photoexcitation of NAD⁺ (fig. S5A). Because OH⁻ can be formed in the course of O₂ reduction (fig. S5B) (18), we further conducted an additional experiment of photochemical OH⁻ generation under N₂-rich conditions. The radical’s amount was ca. 68% of that generated under O₂-rich conditions (fig. SSC), indicating that the contribution of H₂O oxidation is greater than that of O₂ reduction. On the basis of the widely accepted mechanism of molecular photoredox catalysis (5), a possible mechanism for O₂ reduction and H₂O oxidation is suggested to be a combination of oxidative and reductive quenching cycles (fig. S5, D and E). Light absorption of NAD⁺ transforms it into a photoactivated state, [NAD⁺]*. In an oxidative quenching process, O₂ is reduced to O₂⁻ by receiving electrons from [NAD⁺]*. Subsequently, the oxidized cata-

lyst, [NAD⁺]*⁺, oxidizes H₂O to OH⁻ and returns to the original state of NAD⁺. In a reductive quenching stage, the reduced catalyst, [NAD⁺]*-, is formed through H₂O oxidation, which is then transformed into its original state via O₂ reduction. The HOMO and LUMO levels of NAD⁺ makes [NAD⁺]* thermodynamically favorable for photocatalytic production of O₂⁻ and OH⁻.

Metal ion reduction by photoexcited NAD⁺

We investigated the possibility of photochemically reducing Ag⁺ ions to AgNPs by NAD⁺ to procure additional evidence of NAD⁺-driven photocatalytic redox reactions. According to the literature (19), a photocatalyst transfers its photoexcited electrons to Ag⁺ ions, which become Ag atoms and form seed nuclei. These nuclei function as templates for the growth of AgNPs based on the Lifshitz-Slyozov-Wagner theory or the autocatalytic reduction-nucleation process proposed by Finke and Watzky. Because the interaction between electron donor (i.e., NAD⁺) and acceptor (i.e., Ag⁺ ion) plays an important role in redox catalysis, we used UV-Vis spectroscopy to examine the cation–π interaction between Ag⁺ ions and the π-conjugated moieties of NAD⁺. The absorbance of NAD⁺ at ca. 260 nm gradually decreased with the concentration of Ag⁺ ions (fig. S6A), which indicates the alteration of the π–π* transition of the nicotinamide and adenine moieties of NAD⁺ through noncovalent ion-quadrupole interaction. The increase in concentration of Ag⁺ ions (from 0 to 10 μM) caused the spectrophotometric change in the absorbance at around 210 nm (fig. S6B).

After identifying the favorable noncovalent interaction between NAD⁺ and Ag⁺ ions, we exposed a solution of NAD⁺ and silver nitrate (AgNO₃) in deionized water to light from a solar simulator (λ, 260 to 900 nm; P₂60–900nm = 5 mW cm⁻²; P₂60–900nm = 100 mW cm⁻²). We did not use additional sacrificial electron donors because H₂O is an electron donor of photoactivated NAD⁺. As displayed in fig. S6 (C and D), we observed a localized surface plasma resonance (LSPR) band of the AgNPs, which shows the resonant harmonic oscillation of surface electrons in AgNPs upon incident electromagnetic radiation on AgNPs (20). In contrast, a negligible LSPR band was detected in the absence of NAD⁺ or light (fig. S6, E to H). The high-resolution transmission electron microscopic image of thus-synthesized AgNPs in fig. S6I shows that the AgNPs were quasi-spherical with a diameter of 15.8 ± 3.8 nm.

After observing the rather slow formation of AgNPs, we hypothesized that the use of a sacrificial electron-supplying agent may improve the formation rate of AgNPs if the oxidation kinetics of an electron donor is faster than that of water by photoactivated NAD⁺. Note that a kinetic bottleneck of water oxidation could be a cause of the low reduction rate of the counterpart, which is a well-known issue in photo(electro)catalysis (21, 22). We used 3-(N-morpholinio) propanesulfonic acid (MOPS) as a model electron-supplying agent; it has a tertiary amine that can provide its electrons to an excited photocatalyst. We observed its oxidation potential at 0.79 V versus Ag/AgCl (fig. S7A), which indicates that the electron transfer from MOPS to photoactivated NAD⁺ is thermodynamically favorable. As displayed in Fig. 3A, the intensity of the LSPR band in a MOPS buffer increased more than 10 times faster than that in H₂O (fig. S6C; the absorption spectra of AgNPs in a MOPS buffer were obtained after 10-fold dilution of samples). The concentration of the AgNPs synthesized in a MOPS buffer increased with the irradiation time (fig. S7B; see the detailed analytical procedures in the Materials and Methods section). In addition, both NAD⁺ and light were required to obtain a distinctive LSPR band of AgNPs (fig. S7, C and D). The diameter of AgNPs synthesized in a MOPS buffer (17.0 ± 4.8 nm; Fig. 3B and fig. S7E) with 1-min irradiation
particles to larger ones; thus, the populations of both smaller and larger particles increase simultaneously. On the basis of these results, we have depicted a plausible pathway of photoinduced electron transfer for the growth of AgNPs (Fig. 3, C and D). [NAD⁺] transfers its photoexcited electrons to Ag⁺ ions in an oxidative quenching step or receives electrons to H₂O (or MOPS) in a reductive quenching step. In a catalytic turnover step, the subsequent [NAD⁺]⁺ or [NAD⁺]⁻ drives H₂O (or MOPS) oxidation or AgNPs formation, respectively, restoring the initial state of NAD⁺. Note that the formation of AgNPs is thermodynamically favorable because the reduction potential of Ag⁺ ions (0.59 V versus Ag/AgCl) is more positive than LUMONicotinamide. Or LUMOAdenine. Overall, our results indicate that NAD⁺ has strong photocatalytic properties for metal ion reduction.

Direct photoactivation of redox enzymes by NAD⁺
NAD⁺ is a prominent redox cofactor for activating numerous oxidoreductases [e.g., alcohol dehydrogenase (24), formate dehydrogenase (25), and xylitol dehydrogenase (26)] through hydride transfer. We found an alternative route for activating redox enzymes: NAD⁺ that functions not as a cofactor but as a photocatalyst, delivering its photoexcited electrons directly to the enzyme prosthetic group. This approach couples redox biocatalysis with photocatalysis, enabling nonphotocatalytic enzymes to perform photobiocatalytic redox reactions (7). As a model enzyme, we have used a flavin-containing OYE homolog from *Thermus scotoductus* (TsOYE) that requires NADH as a cofactor for catalytic activities. The flavoenzyme reduces prosthetic flavin mononucleotide (FMN) to catalyze asymmetric trans-hydrogenation of activated C=C bonds; the catalyzed enantioselective hydrogenation was highlighted by the 2001 Nobel Prize in Chemistry (27).

We verified the reduction of the enzyme-bound FMN of TsOYE by photoactivated NAD⁺ in a MOPS buffer using UV-Vis spectroscopy (see the rationale for using MOPS in the Materials and Method section). According to the literature (28), the reduction of the prosthetic FMN to FMNH⁺ (or FMNH₂) through proton-coupled electron transfer causes an absorbance decrease at 464 nm. We observed these characteristic phenomena only under irradiation, and the presence of NAD⁺ decreased the absorbance more than the absence of NAD⁺ (Fig. S8A). Because of the rather slow reduction of the prosthetic FMN, we substituted MOPS with triethanolamine (TEOA) to improve the rate of the overall photoinduced cascade of electron transfer. Note that TEOA is an extensively used electron donor in photocatalytic reduction reactions [e.g., H₂ evolution (29) and cytochrome P450 activation (30)]. The use of TEOA augmented the decrease in the relative absorbance (A/A₀) of prosthetic FMN by 46% for 3-min illumination compared to the use of MOPS (Fig. 4A). We attribute the result to the higher oxidation rate of TEOA than that of MOPS by photoactivated NAD⁺. On the other hand, A/A₀ of TsOYE-bound FMN decreased under irradiation without NAD⁺ (Fig. S8B); the overall rate of the A/A₀ decrease was lower, and the convergence value of A/A₀ was higher than those in the presence of NAD⁺. We attribute the FMN’s absorbance decrease in the absence of NAD⁺ to direct photoreduction of FMN by TEOA. According to the literature (7), sacrificial electron donors can directly reduce flavin derivatives under illumination. In addition, A/A₀ under the filtered light (324 nm < λ < 900 nm) was comparable to that in the absence of NAD⁺ (Fig. 4A), which is ascribed to the negligible photosensitization of NAD⁺.

The reduction of the prosthetic FMN in TsOYE was not mediated by NADH through hydride transfer because photochemical activation of NAD⁺ does not generate its reduced form (i.e., NADH). We illuminated a TEOA-buffered solution of NAD⁺ and observed a negligible characteristic peak of NADH at 6.96 parts per million (31) in the ¹H nuclear magnetic resonance (NMR) spectrum (Fig. 4B). Furthermore, the characteristic absorbance of NADH at 340 nm in the UV-Vis spectrum (32) was imperceptible (Fig. S8C). Taking into account the
spectroscopic analyses, we have depicted a possible pathway of electron transfer for direct activation of TsOYE by photoexcited NAD\(^+\) in fig. S8 (D to F). Light promotes electrons of NAD\(^+\) from a ground state to an excited state; the photoexcited electrons have a potential energy enough to reduce a prosthetic FMN (−0.43 V versus Ag/AgCl). TEOA donates its electron (0.86 V versus Ag/AgCl) (7), reinstating the initial state of NAD\(^+\).

The iterative delivery of photoexcited electrons from NAD\(^+\) to TsOYE should execute a sustainable asymmetric hydrogenation of C=C bonds in \(\alpha,\beta\)-unsaturated compounds (Fig. 5A). We tested 2-methyl-2-cyclohexen-1-one as an enone substrate because the tertiary carbon atom of the substrate becomes a chiral center after TsOYE-catalyzed reduction. We observed a stereoselective conversion of 2-methyl-2-cyclohexen-1-one to 2-methylcyclohexanone (93 ± 1% enantiomeric excess) after 150-min illumination (Fig. 5B). The yield of the enantioenriched product was highest when the reaction occurred through the course of an electron cascade from TEOA to TsOYE via photoexcited NAD\(^+\) (Fig. 5C), which is consistent with the highest reduction rate of the enzyme-bound FMN under these conditions (Fig. 4A). A turnover frequency of TsOYE (TOF\(_{\text{TsOYE}}\)) and its total turnover number (TTN\(_{\text{TsOYE}}\)) were estimated to be 1263.4 ± 120.1 hour\(^{-1}\).

**Fig. 4. Direct photoactivation of TsOYE-bound FMN using NAD\(^+\).** (A) Changes in absorbance of TsOYE-bound FMN with or without NAD\(^+\), TEOA, light, and 324-nm filter. Reaction conditions of the experimental group: 13.5 μM TsOYE, 2 mM NAD\(^+\), and 5 mM CaCl\(_2\) in N\(_2\)-purged TEOA buffer (100 mM and pH 7.5). A TEOA buffer was replaced by a MOPS buffer for a control experiment. Error bars correspond to the SD (n = 3). (B) \(^1\)H nuclear magnetic resonance (NMR) spectrum of a reaction sample consisting of 2 mM NAD\(^+\) in a TEOA buffer (100 mM, pH 7.5) under illumination (xenon lamp: λ, 260 to 900 nm; \(P_{260–300}\) nm, 0.023 \(\mu\)E cm\(^{-2}\) s\(^{-1}\) (10 mW cm\(^{-2}\)); \(P_{260–900}\) nm, 0.970 \(\mu\)E cm\(^{-2}\) s\(^{-1}\) (200 mW cm\(^{-2}\))) for 180 min. ppm, parts per million.

**Fig. 5. Hydrogenation of activated C=C bonds via direct, light-driven activation of TsOYE using NAD\(^+\).** (A) Photobiocatalytic reduction of activated C=C bonds by TsOYE. Photoactivated NAD\(^+\) transfers its photoexcited electrons to the prosthetic FMN. A substrate is trans-hydrogenated by receiving a hydride from the reduced FMN and a proton from a Tyr residue. The oxidized NAD\(^+\) returns to its initial state after receiving electrons from electron donors. (B) Time profile of the photoenzymatic reduction of 2-methyl-2-cyclohexen-1-one and enantiomeric excess (ee) of the chiral product. (C) A series of deletional control experiments. Reaction conditions of the experimental group in (B) and (C): 1.5 mM NAD\(^+\), 3 μM TsOYE, 5 mM CaCl\(_2\), and 6 mM substrate in a TEOA buffer (150 mM, pH 7.5) at 318.15 K. \(P_{260–900}\) nm, 1.212 \(\mu\)E cm\(^{-2}\) s\(^{-1}\) (250 mW cm\(^{-2}\)). The measurement was performed in triplicate, and all reported values represent means ± SD. (D) Comparison of photobiocatalytic efficiencies for hydrogenation reaction driven by OYE. Asterisks (*) denote the approximate estimation according to data corroborated by the corresponding reference. MV, methyl viologen; TOYE, OYE from *Thermoanaerobacter pseudethanolicus* E39; YqIM, OYE from *Bacillus subtilis*. 
and 1692.3 ± 63.3, respectively, with 1.5 mM NAD⁺ and 3 μM TsOYE. These values are substantially higher than other reports on the combination of OYE and photocatalysts (28, 32–35) shown in Fig. 5D. The TTN of NAD⁺ (TTN_NAD⁺) increased with the decreasing NAD⁺ concentration; it reached 168 with 9 μM TsOYE (fig. S9A). Furthermore, the NAD⁺/TsOYE hybrid exhibited a catalytic activity toward an unsaturated aldehyde (i.e., trans-cinnamaldehyde). The production yield of 3-phenylpropanaldehyde was lower than that of 2-methylcyclohexanone (fig. S9B), which is attributed to the lower specific activity of TsOYE toward the aldehyde (36) and the inhibitory influence of the product on TsOYE (28).

**DISCUSSION**

The present work unveils the capability of NAD⁺ as a metal-free molecular photocatalyst. Through spectroscopic and electrochemical analyses, nicotinamide and adenine moieties of NAD⁺ absorb light (HOMO–LUMO gap, 4.13 eV) and consequently excite delocalized electrons in conjugated π bonds (LUMO_Nicotinamide, −0.90 V; HOMO_Nicotinamide, 3.23 V; LUMO_Adenine, −2.89 V; HOMO_Adenine, 1.24 V versus Ag/AgCl). On the basis of the HOMO and LUMO levels of NAD⁺ as thermodynamic indices, we have substantiated NAD⁺-sensitized reduction of O₂ coupled with H₂O oxidation. The capability of a photocatalyst to oxidize H₂O as an electron donor is desirable in photochemical reduction reactions because of its abundance (i.e., 55 M in pure water) and no requirement of additional sacrificial electron suppliers. With H₂O identified as an electron donor of photoactivated NAD⁺, we have demonstrated photocatalytic reduction of Ag⁺ ions to form AgNPs in deionized water, which are widely used for catalytic and biomedical applications [e.g., plasmonic oxidation reactions (37) and antibacterial activity (38)].

Furthermore, the use of MOPS as a sacrificial electron donor boosted the formation rate of AgNPs. This reduction experiment takes advantage of the cation–π interaction between Ag⁺ ions and aromatic moieties of NAD⁺.

Furthermore, this work reports the first example of NAD⁺-sensitized activation of redox enzymes through the reduction of the prosthetic groups, which is a departure from the traditional context of NADH regeneration coupled with enzymatic reactions. In the course of the NADH regeneration process, NAD⁺ is reduced to an enzymatically active form of NADH by an additional catalytic system (e.g., secondary enzyme or organometallic electron mediator) (27). Specifically, the photochemical regeneration of NADH requires a photocatalyst, an electron mediator, a sacrificial electron donor, and light (fig. S9C). Compared with the multicomponent regeneration method, the photobiocatalytic platform using NAD⁺ as a photocatalyst drastically simplifies the scheme by not using an electron mediator and a photocatalyst that reduces the electron mediator (fig. S9D). Besides its systematic simplicity, our direct photoactivation of OYE by NAD⁺ achieved the highest TOF_OYE and TTN_OYE ever recorded in photobiocatalytic transformation driven by OYE. We anticipate that this simple and efficient platform can enhance the enzymatic productivity through the molecular tuning of NAD⁺ in the future. Concurrently, the platform can vitalize the synthetic route for metal-free trans-hydrogenation, which is very rare in the production of pharmaceuticals and fine chemicals (39).

In conclusion, the current work identifies a new role of NAD⁺ beyond biological energy transduction. Under dark conditions, NAD⁺ itself cannot oxidize H₂O and reduce O₂ and metal ions. The oxidized form of natural cofactor cannot activate OYE for biocatalytic transformation because the prosthetic group requires a hydride ion from a redox cofactor. This nonproductive property of NAD⁺ is overturned by shining light on NAD⁺; it can function as a photocatalyst to reduce O₂ to oxidize H₂O, to grow metallic nanoparticles, and to directly activate redox enzymes for solar-to-chemical conversion.

**MATERIALS AND METHODS**

**Chemicals**

β-NAD⁺ hydrate (NAD⁺), nicotinamide, adenine, d-(-)–ribose, deuterium oxide (D₂O), tetrabutylammonium hexafluorophosphate (TBAPF₆), acetonitrile, sodium phosphate monobasic, sodium phosphate dibasic, ferrocene, NBT, Tris, acetic acid, acetylacetone, ammonium acetate, MOPS, AgNO₃, TEOA, calcium chloride (CaCl₂), ethyl acetate, magnesium sulfate (MgSO₄), 1-octanol, 2-methyl-2-cyclohexen-1-one, trans-cinnamaldehyde, and 3-phenylpropanaldehyde were purchased from Sigma-Aldrich (St. Louis, MO, USA) and used without further purification. TsOYE was produced following a literature procedure reported previously (32).

**Spectroscopic analysis**

UV-Vis spectra were recorded on a V-650 UV-Vis absorption spectrophotometer (JASCO Inc., Japan) using a quartz glass cuvette (path length, 1 cm). A 1H NMR spectrum was obtained using a 400-MHz and 54-mm NMR DD2 instrument (Agilent Technologies, USA) at 298.15 K. Note that an aqueous reaction sample was dissolved in D₂O, and a water suppression technique was used to improve the signal-to-noise ratio.

**Electrochemical characterizations**

All electrochemical experiments were performed on a potentiostat/galvanostat (WMPG 1000, WonAtech Co., Korea). A three-electrode setup was used with a glassy carbon disk electrode (working electrode: electrode diameter, 3 mm), Ag/AgCl electrode (reference electrode; 3 M NaCl), and a platinum wire (counter electrode) in a single cell. The glassy carbon disk electrode was always polished using 1, 0.3, and 0.05 μm of deagglomerated alumina suspensions before electrochemical analysis. On the basis of the following equations (Eqs. 4 and 5) (40), we measured the formal potential of ferrocene and onset potentials of NAD⁺ to estimate LUMO and HOMO energy levels of NAD⁺:

\[ E_{\text{LUMO}} = -(E_{\text{onset,red}} - E_{\text{formal}} + 5.06) \text{eV} \]  (4)

\[ E_{\text{HOMO}} = -(E_{\text{onset,ox}} - E_{\text{formal}} + 5.06) \text{eV} \]  (5)

Note that \( E_{\text{onset,red}} \) is the onset potential of NAD⁺ reduction, \( E_{\text{onset,ox}} \) is that of NAD⁺ oxidation, and \( E_{\text{formal}} \) is the formal potential of ferrocene. The electrolyte solution consisted of acetonitrile (containing 100 mM TBAPF₆)/sodium phosphate buffer (100 mM, pH 7.5) (v/v, 1:1).

**NBT assay**

To confirm the photochemical formation of O₂⁻, NAD⁺ and 30 μM NBT were dissolved in a phosphate buffer (50 mM, pH 7.5). We injected 500 μl of reaction sample into a 1.5-ml Eppendorf tube (SPL Life Sciences Co., Korea). The reaction volume and the vessel type...
in control groups were identical to those in the experimental group. The tube was irradiated by a xenon lamp (Newport Co., USA) equipped with an infrared water filter. After irradiation, we used a V-650 UV-Vis absorption spectrophotometer (JASCO Inc., Japan) to monitor a change in the absorbance at 360 nm. Note that NBT formazan, which forms by the reaction between \( O_2^- \) and NBT, exhibits a maximum absorption at 560 nm. The \( O_2^- \) or \( N_2^- \)-rich solution was prepared by purging with \( O_2 \) or \( N_2 \), respectively, for 1 hour.

**Analysis of hydroxyl radical**

To estimate the amount of \( OH^- \) produced by photoactivated NAD\(^+\), NAD\(^+\) and 10 mM Tris were dissolved in a sodium phosphate buffer (50 mM, pH 7.5). The solution was exposed to light (\( \lambda = 260 \) to 900 nm; \( P_{260-900 \text{ nm}} = 200 \text{ mW cm}^{-2} \); \( P_{260-300 \text{ nm}} = 10 \text{ mW cm}^{-2} \)) from a xenon lamp (Newport Co., USA) equipped with an infrared filter at 293.15 K. The sample was then mixed with Nash’s reagent (1:1); the reagent was composed of 50 \( \mu \text{M} \) acetic acid, 20 \( \mu \text{M} \) acetylacetone, and 2 \( \text{M} \) ammonium acetate. The incubation of the mixture at 323.15 K for 1 hour developed a yellow color, which was measured spectrophotometrically at 412 nm. We purged \( O_2 \) or \( N_2 \) gas into a reaction medium for 1 hour for an \( O_2^- \) or \( N_2^- \)-enriched environment, respectively.

**Photoreduction of Ag\(^+\) ions to AgNPs**

For photochemical formation of AgNPs, NAD\(^+\) and AgNO\(_3\) were dissolved in a MOPS buffer (50 mM, pH 7.5) and irradiated with a xenon lamp (Newport Co., USA) equipped with a water filter at 293.15 K. In this experiment, a sodium phosphate buffer was not used because silver phosphate precipitates (Ag\(_3PO_4\)) form by the reaction between silicic ions and phosphate ions. An LSPR band of AgNPs was monitored by the spectral irradiance of the xenon lamp. Note that a substitute for TEOA because it is extensively used in the OYE biocatalysis, acts as an electron donor of photoactivated NAD\(^+\), and does not produce a precipitate with Ca\(^{2+}\) ions; the divalent ion is required for activity of TsOYE (41). Note that MOPS and TEOA have buffering capacities. The sample was irradiated with a 450-W xenon lamp at 318.15 K. For the unit conversion of light intensity from mW cm\(^{-2}\) to \( \mu \text{E cm}^{-2} \text{s}^{-1} \), the average photon energy was ca. 2.14 eV according to the spectral irradiance of the xenon lamp. Note that \( \mu \text{E cm}^{-2} \text{s}^{-1} \) refers to the number of moles of photons in micromole hitting a defined surface per second. For quantitative analysis of the product using gas chromatography (GC), organic substrates and products were extracted with ethyl acetate solvent containing 1-octanol as an internal standard. The mixture was centrifuged to collect the organic phase and, after which, was dried with MgSO\(_4\) to eliminate residual water content. The organic supernatant was analyzed by GC using a 7890A gas chromatograph (Agilent Technologies, USA). The machine was equipped with a flame ionization detector and a CP-Chirasil-Dex CB column (25 m by 0.32 mm by 0.25 \( \mu \text{m} \)). The oven temperature program for all enzymatic substrates and products was 363.15 K held for 2 min, 4 K min\(^{-1}\) to 388.15 K held for 0 min, and 20 K min\(^{-1}\) to 453.15 K held for 1 min. The yield, enantiomeric excess (ee), TOF, and TTN were calculated according to the following equations (Eqs. 6 to 10)

\[
\text{Yield(\%)} = \frac{\text{Concentration of product}}{\text{Initial concentration of substrate}} \times 100
\]

\[
\text{ee(\%)} = \left( \frac{\text{Moles of an enantiomer} - \text{Moles of the other enantiomer}}{\text{Total moles of product}} \right) \times 100
\]

\[
\text{TOF}_{\text{OYE}} \text{(hour}^{-1}) = \frac{\text{Concentration of product at the given time}}{\text{Concentration of TsOYE} \times \text{Time}}
\]

\[
\text{TTN}_{\text{OYE}} = \frac{\text{Maximum concentration of product}}{\text{Concentration of TsOYE}}
\]

\[
\text{TTN}_{\text{NAD}^+} = \frac{\text{Maximum concentration of product}}{\text{Concentration of NAD}^+}
\]
