Abstract—As a unique mechanism for MRAMs, magnetic coupling needs to be accounted for when designing memory arrays. This paper models both intra- and inter-cell magnetic coupling analytically for STT-MRAMs and investigates their impact on the write performance and retention of MTJ devices, which are the data-storing elements of STT-MRAMs. We present magnetic measurement data of MTJ devices with diameters ranging from 35 nm to 175 nm, which we use to calibrate our intra-cell magnetic coupling model. Subsequently, we extrapolate this model to study inter-cell magnetic coupling in memory arrays. We propose the inter-cell magnetic coupling factor $\Psi$ to indicate coupling strength. Our simulation results show that $\Psi \approx 2\%$ maximizes the array density under the constraint that the magnetic coupling has negligible impact on the device’s performance. Higher array densities show significant variations in average switching time, especially at low switching voltages, caused by inter-cell magnetic coupling, and dependent on the data pattern in the cell’s neighborhood. We also observe a marginal degradation of the data retention time under the influence of inter-cell magnetic coupling.

Index Terms—STT-MRAM, magnetic coupling, high-density

I. INTRODUCTION

Spin-transfer torque magnetic random access memory (STT-MRAM) is considered as one of the most promising non-volatile memory technologies, since it features high density, nearly unlimited endurance, and negligible leakage power [1]. Thus, many foundries worldwide have been investing heavily in its commercialization. For example, SK hynix demonstrated in 2016 [2] a 4Gb STT-MRAM prototype targetting the replacement of DRAM and flash memories. Samsung and Intel also presented their STT-MRAM solutions in 2018 [3] and 2019 [4], respectively. In STT-MRAMs, data is stored in magnetic tunnel junction (MTJ) devices which contain multiple ferromagnetic layers. Each of them generates a stray field, which has a significant impact on the device’s performance. It has been shown that the stray field increases as the MTJ dimension shrinks [5], which makes intra-cell magnetic coupling a critical constraint for STT-MRAM designs at advanced technology nodes. Furthermore, to compete with DRAM and flash memories, high-density STT-MRAM arrays are required. It was reported that the STT-MRAM array pitch can be made as small as $1.5 \times$ the MTJ diameter at sub-20 nm nodes, using advanced nano-patterning techniques [6]. As the pitch decreases, MTJ devices are pushed closer to each other. This makes inter-cell magnetic coupling between neighboring cells become increasingly evident, which may lead to write errors [7]. Therefore, it is crucial to analyze magnetic coupling and evaluate its impacts quantitatively when it comes to high-density STT-MRAMs at advanced technology nodes.

There is limited work published on magnetic coupling considering both intra- and inter-cell effects in dense STT-MRAM arrays based on designs that were manufactured. In [8], Huang et al. observed experimentally that the stray field results in a distinct difference in the thermal stability factor $\Delta$ of the two binary states of MTJ devices. Wang et al. [9] reported that the stray field has a non-uniform distribution over the cross-section of the MTJ device, and it results in a significant variation in the switching time based on micromagnetic simulations. In [10], Golonzka et al. even observed that some of Intel’s devices were locked to one certain state due to a strong stray field. However, these papers did not take into consideration the stray fields from neighboring cells. Augustine et al. [11] analyzed the stray field from four adjacent cells for in-plane MTJ devices and concluded that inter-cell stray fields can cause up to 80% increase in switching time. Yoon et al. [12] explored the effect of inter-cell magnetic coupling on the MTJ’s properties in a compact memory array. Overall, the related prior work has the following shortcomings: 1) not based on real-world MTJ stack designs with perpendicular magnetic anisotropy, dual MgO, and synthetic anti-ferromagnetic (SAF) pinned layer; 2) intra- and inter-cell magnetic coupling are not considered simultaneously; 3) a lack of magnetic characterization data.

In this paper, we address these issues by characterizing and subsequently modeling intra-cell magnetic coupling for isolated MTJ devices fabricated at IMEC. This model is then used to calculate stray fields at the victim cell located in the center of a representative $3 \times 3$ memory array. The contributions of this paper are as follows.

- Magnetic characterization results of MTJ devices with various sizes ranging from 35 nm to 175 nm.
- An analytical intra-cell magnetic coupling model, which is calibrated and validated by silicon data.
- Extrapolating the above model to study inter-cell magnetic coupling on a cell array with varying pitches.
- Introduction of the inter-cell magnetic coupling factor $\Psi$ to indicate the coupling strength.
- Evaluation of the impact of magnetic coupling on the MTJ’s write characteristics and retention time.

The rest of this paper is organized as follows. Section II provides a background on the MTJ device technology and the magnetic coupling mechanism. Section III presents magnetic characterization data. Section IV elaborates the modeling methodology of intra-cell and inter-cell magnetic coupling. Section V evaluates the impact of magnetic coupling on the MTJ’s performance. Section VI concludes this paper.
II. BACKGROUND

A. MTJ Device Technology

Magnetic tunnel junction (MTJ) devices are the data-storing elements in STT-MRAMs. Each MTJ device stores one-bit data in the form of binary magnetic configurations. Fig. 1a shows the MTJ stack which essentially consists of four layers: FL/TB/RL/HL. The hard layer (HL) is composed of [Co/Pt], which is used to pin the magnetization in the upper reference layer (RL). The RL is generally built up with a Co/spacer/CoFeB multilayer, which is anti-ferromagnetically coupled to the HL. These two layers form a synthetic anti-ferromagnetic (SAF) structure, providing a strong fixed reference magnetization in the RL. The tunnel barrier (TB) layer is made of dielectric MgO, typically ~\(1\) nm. The resistance-area (RA) product is commonly used to evaluate the TB resistivity, as it depends on the TB thickness but not the device size. The CoFeB-based free layer (FL) is the data-storing layer where the magnetization can be switched by a spin-polarized current.

To work properly as memory devices, MTJs need to provide read and write mechanisms, which are realized by the tunneling magneto-resistance (TMR) effect and the spin-transfer-torque (STT) effect [13]. Due to the TMR effect, the MTJ’s resistance is low \((R_{P})\) when the magnetization in the FL is parallel to that in the RL; the resistance is high \((R_{AP})\) when in anti-parallel state. If the write current magnitude (with sufficiently long pulse width) is larger than the critical switching current \((I_{c})\), the magnetization in the FL can switch to the opposite direction. It is a fundamental parameter to characterize the switching capability by current. The STT-induced switching behavior also depends on the current direction, as shown in Fig. 1a. \(I_{c}(AP\rightarrow P)\) can be significantly different from \(I_{c}(P\rightarrow AP)\) due to the bias dependence of STT efficiency and external field disturbance [13]. In addition, the average switching time \((t_{w})\) [14] is another critical parameter, which is inversely correlated with the write current. In other words, the higher the write current over \(I_{c}\), the less the time required for the magnetization in FL to flip. In practice, \(t_{w}(AP\rightarrow P)\) can also differ from \(t_{w}(P\rightarrow AP)\) depending on the write current magnitude and duration.

In addition, enough retention time is required for STT-MRAMs depending on the target application. Storage applications require >10 years typically, while cache applications only necessitate ms-scale retention time [15]. An STT-MRAM retention fault occurs when the magnetization in the FL of the MTJ flips spontaneously due to thermal fluctuation. Thus, the STT-MRAM retention time is generally characterized by the thermal stability factor \((\Delta)\) [13]. The higher the \(\Delta\), the longer the retention time.

B. Magnetic Coupling Mechanism

To obtain high TMR and strong interfacial perpendicular magnetic anisotropy (iPMA), our MTJ devices were annealed at \(375^\circ C\) for 30 min in a vacuum chamber under the perpendicular (out-of-plane) magnetic field of \(20\) kOe. Once the ferromagnetic layers (i.e., FL, RL, and HL) in the MTJ stack are magnetized, each of them inevitably generates a stray field in the space. Fig. 1a illustrates the intra-cell stray field \((H_{s_{\text{intra}}})\) perceived at the FL, generated by the RL and HL together; its in-plane component \((H_{s_{\text{intra}}}^{x})\) is marginal [9], while its out-of-plane component \((H_{s_{\text{intra}}}^{z})\) at the FL has a significant influence on the energy barrier \((E_{b})\) between the P and AP states [1]. For example, if \(H_{s_{\text{intra}}}^{z}\) has the same direction as the magnetization in the FL in AP state, it leads to an increase in \(E_{b}(AP\rightarrow P)\) and a decrease in \(E_{b}(P\rightarrow AP)\). The deviation of energy barriers along the two switching directions has a significant impact on the retention and the STT-switching characteristics of MTJ devices, as reported in [8–10]. In the extreme case where \(H_{s_{\text{intra}}}^{z}\) exceeds the FL coercivity \((H_{c})\), defined as the reverse field needed to drive the magnetization of a ferromagnet to zero, the bistable states will disappear [5].

Furthermore, as the density of STT-MRAMs increases, the spacing between neighboring MTJ devices becomes narrower (i.e., smaller pitch). This makes stray fields from neighboring cells not negligible any more [1,11]. Fig. 1b shows a \(3\times3\) MTJ array, where the eight cells C0-C7 (aggressors) surrounding cell C8 (victim) in the center inevitably generate an inter-cell stray field \((H_{s_{\text{inter}}})\) acting on the victim cell. Fig. 1c and Fig. 1d show the scanning electron microscope (SEM) images of our 0TIR wafer floor plan and MTJ array, respectively.

III. INTRA-CELL MAGNETIC COUPLING CHARACTERIZATION

\(H_{s_{\text{intra}}}^{z}\) can be extracted from R-H hysteresis loops. Fig. 2a shows a measured R-H hysteresis loop for a representative MTJ device with the HL/RL configuration shown in Fig. 1a. During the measurement, an external field was applied perpendicularly to the device under test. It was ramped up from 0 Oe to 3 kOe, then it went backwards to ~3 kOe and finished at 0 Oe. In total, we measured 1000 field points, each of which was followed by a read operation to read out the device resistance with a voltage of 20 mV. It can be seen that the MTJ device switches from AP state (high resistance) to P...
is a macroscopic current $I_b$ (referred to as bound current) flowing around the boundary. The magnetic moment of this ferromagnet can be expressed as $\mathbf{m} = M_s \cdot A \cdot t$ [17], where $M_s$ is the saturation magnetization, $A$ is the cross-sectional area, and $t$ is the thickness of this ferromagnet. Considering the bound current $I_b$, $\mathbf{m}$ can also be written as $I_b \cdot \hat{n}$ where $\hat{n}$ is the unit vector along the direction of $M_s$ [17]. Therefore, one can easily derive $I_b = M_s \cdot t$. For each ferromagnet in the MTJ stack, the $M_s \cdot t$ product is measured at blanket film level by vibrating sample magnetometry (VSM) measurements.

With the derived bound current $I_b$ for each ferromagnet in the MTJ stack, the generated stray field in the space can be modeled as the field of a current loop with current $I_b$, as shown in Fig. 3b. In this way, the stray field at any point $\mathbf{P}(x_p, y_p, z_p)$ in the space can be calculated by the Biot-Savart law [17]:

$$\mathbf{H}(r) = \frac{\mu_0}{4\pi} \oint I_b \, dl \times \frac{r}{|r|^3},$$

where $dl$ is an infinitesimal length of the current loop, $r$ the vector distance from $dl$ to the point $\mathbf{P}$, and $\mu_0$ the vacuum permeability. To calculate the above integral in a discrete form, we can divide the current loop into a large number of small segments, thereafter sum up the fields of all segments at point $\mathbf{P}$ as an approximation of $\mathbf{H}(r)$.

Assume the current loop is cut into $N$ segments. For the $k$th segment $dl_k$, we derive:

$$dl_k = (x_{k+1} - x_k, y_{k+1} - y_k, z_{k+1} - z_k), \quad r_k = (x_p - x_k, y_p - y_k, z_p - z_k).$$

Therefore, $dl_k \times r_k = (S_{k}^x, S_{k}^y, S_{k}^z)$, where

$$S_{k}^x = (y_{k+1} - y_k) \cdot (z_p - z_k) - (z_{k+1} - z_k) \cdot (y_p - y_k),$$
$$S_{k}^y = (z_{k+1} - z_k) \cdot (x_p - x_k) + (x_{k+1} - x_k) \cdot (z_p - z_k),$$
$$S_{k}^z = (x_{k+1} - x_k) \cdot (y_p - y_k) - (y_{k+1} - y_k) \cdot (x_p - x_k).$$

The field generated by the tiny segment $dl_k$ is

$$d\mathbf{H}_k = (dH_{k}^x, dH_{k}^y, dH_{k}^z).$$

By summing up the fields of all $N$ segments, we derive the overall field at the spot $\mathbf{P}$ generated by the entire current loop:

$$\mathbf{H} = \sum_{k=0}^{N-1} d\mathbf{H}_k = (\sum_{k=0}^{N-1} dH_{k}^x, \sum_{k=0}^{N-1} dH_{k}^y, \sum_{k=0}^{N-1} dH_{k}^z).$$

In this way, we can calculate the intra-cell stray field from the HL ($H_{s,HL}$) and intra-cell stray field from the RL ($H_{s,RL}$), respectively. The overall intra-cell stray field is the vector sum of these two fields (i.e., $H_{s,int} = H_{s,HL} + H_{s,RL}$), which is visualized in Fig. 3c for an MTJ device with eCD=55 nm. Fig. 3d shows the distribution of the $z$-component $H_{s,int}^z$ (i.e., the out-of-plane component) over the horizontal cross-section of the FL. It can be seen that $H_{s,int}^z$ is not uniformly distributed at the FL; its magnitude is smaller at the edge than at the center. We took the values at the center (i.e., at radial position=0 nm) and calibrated them with the measured data. Fig. 2b presents the simulation results of $H_{s,int}^z$ vs. eCD, which match the silicon data.
Therefore, the maximum variation in the component $H^z_{\text{intra}}$ distribution over the cross-section of the FL, with respect to various eCDs.

### B. Inter-cell Magnetic Coupling

To study the inter-cell magnetic coupling effect, we extrapolate the intra-cell magnetic coupling model from a single MTJ device to a 3×3 MTJ array in Cartesian Coordinates. The nine devices are named C0 to C8, as illustrated in Fig. 1b. Cell C8 in the center is considered as the victim whereas the four direct neighbors (C0-C3) and four diagonal neighbors (C4-C7) are aggressor cells. In this way, the inter-cell magnetic coupling effect is translated to the impact of net stray field from the eight neighboring cells (denoted as $H_{s\text{,inter}}$) on the FL of the victim C8. $H_{s\text{,inter}}$ can be calculated by:

$$H_{s\text{,inter}} = \sum_{i=0}^{7}(H_{s\text{,HL}}(C_i) + H_{s\text{,RL}}(C_i) + H_{s\text{,FL}}(C_i)).$$

Since the HL and RL are both fixed layers after the fabrication of MTJ devices, $H_{s\text{,HL}}$ and $H_{s\text{,RL}}$ are fixed, given an eCD and a pitch node. However, the direction of $H_{s\text{,FL}}$ changes dynamically depending on the data stored in the MTJ device though its magnitude remains the same. As a result, $H_{s\text{,inter}}$ depends on the neighborhood pattern in the eight neighboring cells (i.e., C0-C7), which we denote as NP8. In the binary form, NP8 can be expressed as: $[d_0, ..., d_7]_2$, where $d_i \in \{0, 1\}$ represents the data stored in $C_i$. In addition, NP8 can also be transformed to the decimal form: $[n]_{10}$, where $n \in \{0, 255\}$.

Fig. 4a shows the resultant $H_{s\text{,inter}}$ values at the FL of victim C8 as a function of the number of 1s in direct neighbors C0-C3 (marked in yellow) and the number of 1s in diagonal neighbors C4-C7 (marked in blue). Since C0-C3 are in symmetric positions and C4-C7 are also in symmetric positions, there are 25 distinct combinations as shown in the figure. For this example, we set eCD=55 nm and pitch=90 nm (design spec. from the SK hynix high-density STT-MRAM design in [2]). It can be seen that $H^z_{s\text{,inter}}$ reaches its lowest point (−16 Oe) when C0-C7 are all in 0 (P) state (i.e., NP8=0). In this case, the magnetization in the FL of every aggressor cell is in parallel with that of the RL; together, they generate a stray field which is stronger enough to compensate the stray field from the HL. As the bit number of 1s increases, $H^z_{s\text{,inter}}$ increases; it increases in a step of 15 Oe with the number of 1s in direct neighbors and in a step of 5 Oe with the number of 1s in the diagonal neighbors. When C0-C7 are all in 1 (AP) state (i.e., NP8=255), $H^z_{s\text{,inter}}$ reaches the peak (64 Oe). Therefore, the maximum variation in $H^z_{s\text{,inter}}$ among the 256 neighborhood patterns is 80 Oe in this case. If the value is too large compared to the device coercivity ($H_c=2.2$ kOe for the measured devices in this paper), it may result in a significant variation in the device performance. To quantitatively evaluate the inter-cell magnetic coupling strength, we defined inter-cell magnetic coupling factor $\Psi$ as the ratio of the maximum variation in $H^z_{s\text{,inter}}$ to $H_c$. $\Psi$ will be used as an indicator of inter-cell magnetic coupling strength in the rest of this paper.

The $\Psi$ value varies with device size and array pitch, as shown in Fig. 4b. In our simulations, we set the minimum pitch to 1.5×eCD according to [6] for high-density STT-MRAMs and the maximum pitch to 200 nm, which is adopted by both Samsung and Intel [4,18]. It can be seen that $\Psi \approx 0\%$ at pitch=200 nm for all three device sizes, indicating the inter-cell magnetic coupling is negligible due to the far distance between devices. As the pitch decreases, $\Psi$ increases gradually until reaching a threshold point after which it goes up exponentially. For our devices, $\Psi=2\%$ (marked with the dashed line) can be considered as the threshold point, where the array density is maximized with negligible inter-cell magnetic coupling. For a device with eCD=35 nm, this corresponds to pitch=~80 nm.

### V. Evaluation of Magnetic Coupling Impacts

In this section, we evaluate the impact of magnetic coupling on the critical switching current $I_c$ and the average switching time $t_e$, using the proposed model. Thereafter, we investigate the impact on the thermal stability factor $\Delta$ in a similar way. Due to the space limitation, we will only present the simulation results for devices with eCD=55 nm.

#### A. Impact on the Critical Switching Current

Under the influence of stray field, $I_c$ can be expressed as follows [13]:

$$I_c(H^z_{\text{stray}}) = \frac{1}{\eta} \frac{2\alpha e}{\hbar} M_s \cdot V \cdot H_k \cdot \left(1 \pm \frac{H^z_{\text{stray}}}{H_k}\right),$$

where $\eta$ is the STT efficiency, $\alpha$ the magnetic damping constant, $e$ the elementary charge, $\hbar$ the reduced Planck constant, $M_s$ the saturation magnetization, $V$ the volume of the FL, $H_k$ the magnetic anisotropy field. The sign in the parentheses is ‘+’ for $I_c(P\rightarrow AP)$ and ‘−’ for $I_c(AP\rightarrow P)$, given the definition of coordinates in this paper. In Equation (2), $H^z_{\text{stray}} = H^z_{s\text{,intra}} + H^z_{s\text{,inter}}$ can be calculated with our proposed magnetic coupling model taking into account both intra-cell and inter-cell stray fields, while $H_k$ needs to be extracted from measurement data. The other parameters in the
The switching points (i.e., $H_{sw,P}$ and $H_{sw,N}$ in Fig. 2a) are intrinsically stochastic, we measured the R-H loop of the same device for 1000 cycles to obtain a statistical result of the switching probability at varying fields. With the technique proposed in [19], we are able to extract $H_k$ and $\Delta_0$ by performing curve fitting. $\Delta_0$ is the intrinsic thermal stability factor without any stray field at the FL; it will be used in the next subsection. By doing this for a large number of devices, we obtained $\Delta_0 = 45.5$ Oe and $H_k = 4646.8$ Oe (both in median) for devices with $eCD=35$ nm.

Fig. 4c shows the critical switching current $I_c$ for C8 (for both $P \rightarrow AP$ switching and $AP \rightarrow P$ switching) at different pitches with respect to various stray fields. For isolated devices without any stray field (i.e., ideal case, $H_{stray} = 0$), the intrinsic $I_c$ for the two switching directions is supposed to show no difference; $I_c = 57.2 \mu$A. When taking into account the intra-cell stray field (i.e., $H_{stray} = H_{stray}^z$), a static shift in $I_c$ is introduced, making $I_c(AP \rightarrow P)=61.7 \mu$A (i.e., 7% above the intrinsic $I_c$) and $I_c(P \rightarrow AP)=52.8 \mu$A (i.e., 7% below). When considering both intra-cell and inter-cell stray fields (i.e., $H_{stray} = H_{stray}^z$), $H_{stray}^z$ for different neighborhood patterns $NP_8$, the impact on $I_c$ shows a clear dependence on the array pitch. $I_c(AP \rightarrow P)$ becomes larger at smaller pitches when $NP_8=0$, while it shows an opposite trend when $NP_8=255$. This indicates that the variation in $I_c(AP \rightarrow P)$ between different neighborhood patterns increases as the pitch goes down. It can be seen that at pitch=80 nm (corresponding to $\Psi = 2\%$), the variation is marginal. Similar observations can be seen on the $P \rightarrow AP$ switching direction.

B. Impact on the Average Switching Time

The average switching time $t_w$ in the presence of $H_{stray}^z$ in the precessional regime (namely, switched by the STT-effect) can be estimated using Sun’s model as follows [20]:

$$t_w(H_{stray}^z) = \left(\frac{2}{C + \ln(\frac{\pi^2 \Delta}{4} \cdot \frac{\mu_B P}{em(1 + P^2)} \cdot I_m)}\right)^{-1},$$

$$I_m = \frac{V_p}{R_{\psi}} - I_c(H_{stray}^z).$$

Here, $C \approx 0.577$ is Euler’s constant, $\mu_B$ the Bohr magneton, $P$ the spin polarization, $e$ the elementary charge, and $m$ the FL magnetization. $V_p$ is the voltage applied on the MTJ device to switch its state. $R_{\psi}$ is the resistance of the MTJ device $H_{stray}^z$ as a function of the applied voltage $V_p$; it shows a non-linear dependence on $V_p$ [20].

Fig. 5a-c shows the voltage dependence of the average switching time from AP state to P state ($t_w(AP \rightarrow P)$) for MTJs with $eCD=35$ nm at pitch=3×$eCD$, 2×$eCD$, and 1.5×$eCD$. Due to the space limitation, the simulation results of $t_w(P \rightarrow AP)$ are excluded. It can be seen that $t_w(AP \rightarrow P)$ becomes larger for MTJ devices in the presence of $H_{stray}^z$ (solid lines), comparing to devices without any stray field (dashed lines). It is worth noting that the larger the voltage, the smaller the impact of the stray field on $t_w(P \rightarrow AP)$.

C. Impact on the Thermal Stability Factor

The intrinsic thermal stability factor $\Delta_0$ (without any stray field at the FL) of the MTJ device is given by [13]:

$$\Delta_0 = \frac{H_k \cdot V_p}{k_B T},$$

where $k_B$ is the Boltzmann constant and $T$ is the absolute temperature. However, in the presence of stray fields, the thermal stability factor in AP state deviates from that in P state, i.e., $\Delta_{AP} \neq \Delta_P$. The $\Delta$ value in the presence of $H_{stray}^z$ is given by [13]:

$$\Delta(H_{stray}^z) = \Delta_0(1 \pm \frac{H_{stray}^z}{H_k})^2,$$

where the sign in the parentheses is ‘+’ for $\Delta_P$ and ‘–’ for $\Delta_{AP}$ for the devices considered in this paper. $H_{stray}^z$ can be calculated with our proposed magnetic coupling model, while $H_k$ and $\Delta_0$ are extracted from measurement data.

Fig. 6a shows the thermal stability factor $\Delta$ at varying temperature for $eCD=35$ nm and pitch=2×$eCD$, corresponding
to $\Psi = 2\%$. It can be seen that the intra-cell stray field $H_{\text{intra}}^{s}$ introduces a static shift in $\Delta_{P}$ and $\Delta_{\text{AP}}$; $\Delta_{\text{AP}}$ is $\sim 30\%$ smaller than $\Delta_{P}$ comparing the dash-dotted line to the dotted one. The solid lines represent the thermal stability factors considering both intra-cell and inter-cell magnetic coupling. It can be seen that the MTJ device has the smallest $\Delta$ (highest vulnerability to a retention fault) when the victim cell is in P state and all neighboring cells are also in P state (i.e., $NP_{8}=0$). Fig. 6b compares the worst-case $\Delta$, i.e., $\Delta_{P}(NP_{8}=0)$, at pitch=3×eCD, 2×eCD, and 1.5×eCD. One can observe that $\Delta_{P}(NP_{8}=0)$ shows a marginal degradation when the array pitch goes down to 1.5×eCD, in comparison to pitch=2×eCD.

VI. CONCLUSION

Magnetic coupling including both intra- and inter-cell can be a critical design constraint for high-density STT-MRAM designs as the MTJ device scales down. Intra-cell magnetic coupling needs to be minimized by further device stack innovation, as it leads to a significant invariance in the switching characteristics and retention for AP→P and P→AP switching directions. The inter-cell magnetic coupling depends on the device size as well as the array pitch. When the pitch reaches at $\sim 2$ times of device diameter (corresponding to $\Psi = 2\%$), the array density is maximized with negligible impact on the device performance. However, more aggressive exploration in array density (e.g., pitch=1.5×eCD) shows significant variations in average switching time, especially at low switching voltages, caused by inter-cell magnetic coupling. Moreover, we also observed a marginal degradation of retention due to the increased inter-cell magnetic coupling.

ACKNOWLEDGMENT

We would like to acknowledge and thank the efforts of Sebastien Couet, Farrukh Yasin and Davide Crotti in fabricating the STT-MRAM devices and Nico Jossart for providing the SEM images. This work was performed as part of imec’s industrial affiliation program on STT-MRAM devices.
