Low-friction, wear-resistant, and electrically homogeneous multilayer graphene grown by chemical vapor deposition on molybdenum

Borislav Vasić, Uroš Ralević, Katarina Cvetanović Zobenica, Milče M. Smiljanić, Radoš Gajić, Marko Spasenović, Sten Vollebregt

Chemical vapour deposition (CVD) is a promising method for producing large-scale graphene (Gr). Nevertheless, microscopic inhomogeneity of Gr grown on traditional metal substrates such as copper or nickel results in a spatial variation of Gr properties due to long wrinkles formed when the metal substrate shrinks during the cooling part of the production cycle. Recently, molybdenum (Mo) has emerged as an alternative substrate for CVD growth of Gr, mainly due to a better matching of the thermal expansion coefficient of the substrate and Gr. We investigate the quality of multilayer Gr grown on Mo and the relation between Gr morphology and nanoscale mechanical and electrical properties, and spatial homogeneity of these parameters. With atomic force microscopy (AFM) based scratching, Kelvin probe force microscopy, and conductive AFM, we measure friction and wear, surface potential, and local conductivity, respectively. We find that Gr grown on Mo is free of large wrinkles that are common with growth on other metals, although it contains a dense network of small wrinkles. We demonstrate that as a result of this unique and favorable morphology, the Gr studied here has low friction, high wear resistance, and excellent homogeneity of electrical surface potential and conductivity.

ABSTRACT

Chemical vapour deposition (CVD) is a promising method for producing large-scale graphene (Gr). Nevertheless, microscopic inhomogeneity of Gr grown on traditional metal substrates such as copper or nickel results in a spatial variation of Gr properties due to long wrinkles formed when the metal substrate shrinks during the cooling part of the production cycle. Recently, molybdenum (Mo) has emerged as an alternative for CVD growth of Gr, mainly due to a better matching of the thermal expansion coefficient of the substrate and Gr. We investigate the quality of multilayer Gr grown on Mo and the relation between Gr morphology and nanoscale mechanical and electrical properties, and spatial homogeneity of these parameters. With atomic force microscopy (AFM) based scratching, Kelvin probe force microscopy, and conductive AFM, we measure friction and wear, surface potential, and local conductivity, respectively. We find that Gr grown on Mo is free of large wrinkles that are common with growth on other metals, although it contains a dense network of small wrinkles. We demonstrate that as a result of this unique and favorable morphology, the Gr studied here has low friction, high wear resistance, and excellent homogeneity of electrical surface potential and conductivity.

1. Introduction

Chemical vapour deposition (CVD) is the most dominant method for fabrication of large-area single- and few-layer graphene (Gr) films on various metallic substrates (catalysts) [1-4]. After the growth, Gr films are transferred onto desired substrates that allow practical use [5,6]. The main advantages of CVD over other fabrication techniques are its relative simplicity, low cost, and industrial applicability [7-9]. Still, CVD growth and Gr transfer yield films with defects such as grain boundaries [10-16], wrinkles [17-23] and cracks. Formation of wrinkles, for example, occurs due to a large difference in thermal expansion coefficients of Gr and the catalytic substrate, which results in different shrinking rates during cooling at the end of the CVD growth process. Wrinkles in Gr have been shown to be highly detrimental to the mechanical robustness and electrical homogeneity of graphene [23]. CVD graphene is prone to formation of defects both on most commonly used catalytic metal substrates such as copper [1-3] and nickel [4], as well as on less traditional substrates such as ruthenium, iridium, and platinum [9].

Recently, Gr grown by CVD on thin molybdenum (Mo) films sputtered on silicon wafers [24-26] has emerged as an alternative to Gr grown on traditional metal substrates. Growth on Mo offers several advantages. Namely, the thermal expansion coefficient of Mo is well matched to that of Gr, supporting wrinkle-free growth [25]. Also, Mo has a high melting point, resulting in less restructuring of the Mo substrate compared to copper during the CVD process. Finally, low solubility of carbon in bulk Mo facilitates easy growth of Gr layers [24], making the process attractive for high-volume applications. In addition to the advantages for growth, graphene on a thin sputtered layer of Mo has advantages for subsequent processing. The Mo layer can be patterned prior to growth, enabling patterning of CVD graphene without post-growth lithography, and the Mo can be easily removed once Gr is grown on it, which allows transfer-free fabrication of Gr devices that is compatible with CMOS processes [27,28]. Graphene grown with this novel process was shown to have applications in anti-corrosion coatings [29-31], gas [27,32] and pressure sensors [28]. Although Gr grown on Mo has high potential for practical use, the relation between microscopic morphology, distribution and geometry of wrinkles, and their influence on the mechanical and electrical properties of the material have not yet been studied.
Using atomic force microscopy (AFM) based methods, here we present nanoscale analysis of the morphology, mechanical and electrical properties of few-layer Gr grown by CVD on Mo. We demonstrate that the material contains very few wrinkles and that those wrinkles have dimensions that are much smaller than those typically encountered in Gr grown on copper foils. Gr grown on Mo has low friction and high wear resistance as demonstrated by friction force microscopy and nanoscale wear tests. Using Kelvin probe force microscopy (KPFM) and conductive AFM (c-AFM) we show that this material has high uniformity of the Fermi level (work function) and electrical conductivity, respectively, over large areas. These results allude to strong potential uses of Gr grown on Mo for both mechanical and electrical applications such as ultrathin solid lubricants, electrodes and membranes for nano and microelectromechanical systems.

2. Experimental

2.1. Graphene fabrication and transfer

We studied both Gr on Mo as grown, as well as Gr transferred from Mo to Si/SiO₂. The 50 nm thick Mo catalyst was deposited using magnetron sputtering on top of a Si/SiO₂ wafer (p-type, 10 cm, (1 0 0) orientation). SiO₂ was approximately 600 nm thick and it was grown using wet thermal oxidation. The Mo target purity was 99.95%. Gr was deposited using an AIXTRON Blackmagic Pro system at 915 °C using 960/40/25 sccm of Ar/H₂/CH₄ at 25 mbar for 30 min and cooled to room temperature under an Ar atmosphere. After this, the wafers were cut into smaller dies for sample preparation. Further details of the CVD growth of Gr on Mo can be found in our previous paper [25].

Graphene was transferred by first immersing dice of Gr on wafer in 30% hydrogen-peroxide for 25 min. Hydrogen peroxide etches away the Mo underneath the Gr layer and Gr is released, floating on the surface of the hydrogen peroxide solution. Gr was transferred into a Petri dish, 5 cm in diameter and 17 ml of volume, with H₂O₂. Hydrogen peroxide was exchanged with deionized (DI) water. The DI water was exchanged three times to ensure complete removal of peroxide. Gr was then carefully picked up onto a Si/SiO₂ wafer die. The sample was dried at room temperature for 25 min, and was put under a glass bell for the next 24 h to dry completely.

2.2. AFM and Raman characterization

All AFM measurements were performed with an NTEGRA Spectra system at ambient conditions. Morphology was measured in tapping AFM mode with NSG01 probes. The surface roughness was measured across ten 50 × 50 μm² areas, calculated as the root-mean square of the height distributions, and then averaged. Phase lag of the AFM probes was measured simultaneously with topography in order to achieve better contrast of small topographic features and to check for possible changes in material contrast on the sample surface.

Wear tests were done in contact AFM mode on 5–10 different 10 × 10 μm² areas with diamond coated probes DCP20. In order to initiate Gr wear, the normal load was kept constant during scanning within 1 μN wide parallel stripes and increasing in steps of around 1 μN from stripe to stripe, for a total range between 0.5 μN and 5 μN [23]. During the wear tests, we recorded the lateral forces in both forward and backward directions. These forces correspond to the lateral torsion of the AFM cantilever due to the AFM tip-Gr friction. The friction force was determined as the half-difference between the lateral force in the forward and backward direction. The normal force was calculated according to force-displacement curves, whereas the friction force was calibrated on a standard Si grating [33].

Kelvin probe force microscopy (KPFM) and Pt coated NSG01/Pt probes were employed in order to measure local electrical surface potential. KPFM is a two-pass AFM-based measurement technique which returns a local contact potential difference (CPD) between a metallic AFM tip and the sample surface. The topographic profile of the sample was measured in the first pass. In the second pass, the AFM probe was lifted by 20 nm and scanned along the same topographic line as in the first pass, while a sum of DC and variable AC voltages was applied between the probe and the sample. The role of the AC voltage was to electrically excite probe oscillations, while the DC voltage was controlled by the AFM feedback loop in order to nullify these oscillations. The value of DC voltage which nullifies AFM probe oscillations is equal to the local CPD between the AFM tip and the sample.

Since CPD is equal to the difference between the work functions of the AFM tip (WF_{tip}) and the sample (WF_{sample}), the WF_{tip} of the Pt coated AFM probes was calibrated on a HOPG sample with a well known work function of 4.6 eV [34]. Measurements on HOPG yielded WF_{tip} = 5 eV. The work functions of the Gr samples were calculated as WF_{Gr} = CPD − WF_{tip}. As in the case of the surface roughness and wear tests, the CPD was measured on 5–10 different areas (50 × 50 μm² in the case of Gr grown on Mo, and 30 × 30 μm² on Gr transferred on SiO₂) and then averaged.

Conductive AFM (C-AFM) with highly doped diamond coated probes DCP20 was used for characterization of local conductivity. In C-AFM, during standard topographic imaging in AFM contact mode, a DC voltage in a range between 1 V and 2 V was applied between the probe and the sample. The resulting DC current through the AFM probe, proportional to the local conductivity of Gr samples, was simultaneously measured with a built-in current amplifier. In order to avoid wear of AFM tips and achieve reliable current measurements, C-AFM was done using diamond coated DCP20 probes which were heavily doped by nitrogen. The diamond coating provides the robustness and wear resistance of AFM tips, while the high doping makes them highly conductive. As a result, these probes enabled reliable current mapping in contact AFM mode.

Raman imaging of CVD Gr transferred on Si/SiO₂ was performed on the same NTEGRA Spectra module equipped with a confocal Raman system (NA 0.7). Raman maps were measured with a step of 0.5 μm. The wavelength of the excitation laser was 532 nm.

3. Results and discussion

3.1. Morphology

3.1.1. CVD Gr on Mo

The topography of CVD Gr on Mo is depicted in Fig. 1 on two different length scales. One of the main motivations and potential benefits of CVD on Mo is the growth of wrinkle-free Gr since the thermal expansion coefficient of Mo is much better matched to that of Gr than the thermal expansion coefficients of copper or nickel. Indeed, in these topographic images there are no long wrinkles typically observed in traditional CVD Gr grown on copper.

Still, very short wrinkles can sometimes be observed on small-scale
Wrinkles are marked by arrows. The inset in part (c) depicts the topographic cross-section across the wrinkle, along the solid line. The dotted line is a guide to the eye which follows the surface of the grain in order to emphasize the wrinkle geometry.

Figure 2. Wrinkles in CVD Gr on Mo: (a) topography and (b) phase of 2 × 2 μm² area. (c) Three-dimensional topography and (d) phase of 0.6 × 0.6 μm² area. Wrinkles are marked by arrows. The inset in part (c) depicts the topographic cross-section across the wrinkle, along the solid line. The dotted line is a guide to the eye which follows the surface of the grain in order to emphasize the wrinkle geometry.

Surface roughness of Gr calculated from large-scale images such as from Fig. 1(a) was 2.9 ± 0.1 nm (averaged over ten 50 × 50 μm² areas). Lower roughness could be achieved by using Mo foils as substrates [26], but foils are not compatible with semiconductor technologies. Therefore, we have considered Gr grown on thin films such as sputtered Mo, which is fully compatible with CMOS processing [27,28].

The roughness of Gr originates from patches with slightly increased height and from the grain structure of the underlying substrate. Gr patches in topographic images in Fig. 1 look like brighter domains, with a lateral size of several microns, and a height of several nanometers. A high-resolution image of an 2 × 2 μm² area, depicted in Fig. 2(a), reveals that Gr follows the morphology of the underlying Mo substrate while the grain structure of Mo is imprinted and replicated onto Gr. As a result, the grain structure of Mo dominates the measured topography thus contributing to increased surface roughness. It should be emphasized that as deposited Mo is very flat with sub-nm roughness. However, the Mo turns into Mo₂C upon exposure to CH₄ before the Gr formation starts [26], and due to this recrystallization into Mo₂C, the roughness increases.

Grain structure and especially grain boundaries are even better visualized in the corresponding phase image in Fig. 2(b). Since the phase signal is generally very sensitive to sudden and sharp topographic features such as hills (grains) or narrow holes (grain boundaries), it can be used for their visualization with even better resolution than in pure topographic images. As can be seen, the shape of grains is rather irregular, with an average grain diameter of around 100 nm. The autocorrelation function of the height distribution (not shown here) is isotropic, indicating that on average, there is no preferential in-plane anisotropy of the grain structure.

Fig. 3. Morphology of CVD Gr on SiO₂: (a) 50 × 50 μm² and (b) 7 × 7 μm² area.

3.1.2. CVD Gr on SiO₂

The morphology of CVD Gr transferred on SiO₂ is presented in Fig. 3. The calculated surface roughness was 3.8 ± 1 nm (averaged over ten 50 × 50 μm² areas). Therefore, the roughness slightly increased after the transfer mainly because micron-size patches with a slightly increased height were more evident than in the previous case of Gr on Mo. In addition, Gr on SiO₂ has a rather dense network of short wrinkles as depicted in Fig. 3 and it contains nano-particles, represented by bright, isolated point-like features in Fig. 3(a), which are most probable residues from the transfer process.

As mentioned above, Mo thin films as substrates allow transfer-free Gr fabrication, thus making the fabrication simpler and compatible with semiconductor technologies [27,28]. Here we consider Gr transferred on SiO₂ because it facilitates characterization and analysis, but it should be emphasized that the chemical treatment is the same in both cases (i.e. Gr is immersed in hydrogen-peroxide in both cases, the only difference is that in the transfer-free approach, the original growth substrate is reused, whereas during the transfer, another substrate is used for picking Gr up). Therefore, the results presented here hold for transfer-free Gr as well.

Short Gr wrinkles observed in Fig. 3(b) are better visualized in the small-scale images in Fig. 4(a) and 4(b). The typical height profile of a wrinkle is depicted in Fig. 3(c), whereas the distributions of wrinkle widths and heights are given in Fig. 4(d). The height can be fitted with a linear function of the width. According to Ref. [20], there are three classes of wrinkle geometry: ripples, standing collapsed wrinkles and folded wrinkles. Since the wrinkle width in our case is less than ~50 nm, they have the geometry of ripples, while higher wrinkles are most probably standing collapsed ones. This is a significant difference compared to CVD Gr grown on copper [23] where thermally induced wrinkles are much wider, up to several hundreds of nanometers, and belong to the class of folded wrinkles. On the Gr studied here, wrinkles are generally short, most of them with lengths in the range 100 – 200 nm. They do not have any preferential direction, while shorter wrinkles are usually curved. These wrinkles appear during transfer onto SiO₂. According to wrinkle lengths, shapes, and their mutual distances, it seems that they correspond to grain boundaries of Gr on Mo - narrow, irregular and curved domains along which Gr on Mo
was locally bent and corrugated. The different wrinkle type of Gr grown on Mo compared to that grown on copper is the most probable reason for improved mechanical and electrical properties, as will be discussed in the following sections.

3.2. Raman analysis

Further characterization of CVD Gr transferred on \( \text{SiO}_2 \) was done by combined AFM and Raman mapping. The results are presented in Fig. 5 with the topography (part (a)), integrated Raman intensity (part (b)), the ratio between the intensity of G and 2D Raman modes (part (c)), and Raman spectra taken at three representative points (part (d)). As can be seen, the characteristic Raman modes of Gr, G (around 1586 cm\(^{-1}\)) and 2D (around 2700 cm\(^{-1}\)) modes are clearly resolved. Still, the appearance of the defect mode D (around 1350 cm\(^{-1}\)) indicates non-negligible defects in CVD Gr. The 2D peak is slightly shifted to longer wavenumbers which indicates that the considered CVD Gr is multilayered. The ratio G/2D is in the range between 0.5 and 0.7, which corresponds to a thickness of 4–6 layers [35]. The same thickness is confirmed by AFM measurements as shown in Fig. S1 of Supplementary material. By comparing encircled domains in all maps, most of the patches with increased height correspond to domains with decreased total Raman intensity and increased G/2D ratios. Therefore, the number of Gr layers is locally increased within those patches. Still, some patches where the G/2D ratio is not increased (or has even slightly decreased) likely contain just locally wrinkled and/or folded layers. Raman spectra

of samples stored in ambient conditions for over two years reveal no deterioration due to aging.

3.3. Friction and wear properties

Wear tests were done by scratching CVD Gr on SiO₂ in contact AFM mode. The results are presented in Figs. 6(a) and 6(b), that depict topography obtained during scratching and an enlarged topographic image recorded in tapping mode after scratching, respectively. The scratching was done from the bottom to the top. The normal load was increased in a range starting from 0.9 μN applied to the bottom Gr stripe with 1 μm width, to 5.4 μN applied on the top of the image where tearing occurred. The points where the normal load was increased are marked by arrows in Fig. 6(a). When the normal load reached a threshold value of 5.4 μN, Gr started to tear. The moment of tearing is clearly visible as a sudden change in the contrast of both topographic images in Fig. 6. The normal load was then kept at a high value, while Gr was peeled off by the AFM probe within the scan area. The area where Gr was peeled off is apparent in Fig. 6(b) as a rectangular stripe with bare SiO₂. Peeled Gr was rolled and deposited at the top of this domain, where scratching was stopped, and it is visible as a bright and narrow horizontal stripe.

The same wear experiment was repeated on five different areas of the Gr sample. The results were similar in all cases - sudden Gr tearing at a high enough normal load, while the threshold force needed for Gr tearing varied in the range 3.4 – 5.4 μN. The mechanism of Gr tearing can be explained in the following way. High normal forces applied by the AFM tip during wear test lead to plastic deformations of Gr beneath the tip [36]. The plastic deformations are characterized with various defects, mostly by vacancy defects, which degrade the mechanical properties of Gr and its breaking strength [37]. By increasing normal force, Gr becomes more defective while the breaking strength of Gr becomes very small, which results in Gr fracture and tearing. The average threshold force for the tearing of CVD Gr considered here is around 4 μN and it is much higher, at least by an order of magnitude, than in CVD Gr grown on copper and transferred on SiO₂, where Gr tearing was always initiated from long and wide, thermally grown wrinkles, for normal loads less than 0.5 μN [23] and sometimes already at around 100 nN [38]. Although in the former cases single-layer Gr samples were considered, the wear resistance of CVD Gr grown on Mo seems to be higher because of the different type of wrinkles in CVD Gr grown on Mo. Here they are small and narrow (simple ripples [20]) and can be easily pressed by the AFM tip without tearing, while the Gr sheet is simultaneously just flattened.

The lateral force recorded during the scratching test is displayed in Fig. 7(a). The force increases with the normal load in stepwise fashion before Gr tearing. The friction force was calculated according to the lateral force recorded in forward and backward directions. The friction map is depicted in Fig. 7(b), whereas the corresponding histogram is presented in Fig. 7(c). The friction map is characterized by two distinct domains: the bottom part with low friction on Gr covered SiO₂ and the top part with high friction on bare SiO₂. According to the histogram, friction on Gr is more than 4 times smaller than on SiO₂, indicating good lubrication properties of Gr.

The average profile of the friction map along the vertical direction is given in Fig. 7(d). The friction force increases stepwise with the normal load. When the threshold force for Gr tearing is reached, the friction increases abruptly and stays at a constant level representing friction on bare SiO₂. The initial stepwise increase of the friction can be approximated by a linear function represented by the dashed line in Fig. 7(d). The slope of this linear curve is the ratio between the friction force and applied normal load and it yields a friction coefficient of Gr of only 0.13. This value is similar to that obtained earlier for Gr grown on copper and nickel [39]. Friction is also influenced by defects in Gr [40], mainly by exposed Gr edges and wrinkles, which lead to increased friction [38,41]. As mentioned above, the considered CVD graphene is almost free of cracks and exposed edges. At the same time, friction maps (the typical one shown in Fig. 7(b)) do not show increased friction due to Gr wrinkles, because they are small and narrow and could be easily pressed by the AFM tip. According to these results, CVD Gr grown on Mo could be an excellent choice for making large-scale and ultrathin solid lubricants with increased wear resistance for friction [39,42,43] and wear reduction [36,44-46] of underlying substrates.

3.4. Electrical surface potential

3.4.1. CVD Gr on Mo

Homogeneity of electrical surface potential was investigated by KPFM. Topography of CVD Gr on Mo and the corresponding CPD map are given in Figs. 8(a1) and (a2), respectively, whereas the histogram of the CPD map is shown in Fig. 8(a3). The histogram contains a single, narrow peak indicating that the measured CPD is rather uniform over a wide 50 × 50 μm² area. Averaged CPD (taking into account 10 different areas) was 352 ± 6 mV. The absolute value of the work function of the considered CVD Gr on Mo is thus 4.66 eV. The maximal half-width of all CPD maps measured on 50 × 50 μm² areas was only around 5 mV, indicating a very uniform electrical surface potential distribution. Still, CPD maps clearly show irregularly shaped potential puddles. The
3.5. Electrical conductivity

3.5.1. CVD Gr on Mo

Homogeneity of electrical conductivity was studied by C-AFM. Topography and corresponding current maps are presented in Figs. 9(a) and 9(b), respectively. The current map exhibits rather homogeneous surface potential over large areas [23]. Even metal films, such as sputtered gold, display larger variability of surface potential over large areas [59], whereas films deposited with atomic layer deposition display variability on the order of ~10 mV [60].

Fig. 8. (a1) Morphology of CVD Gr on Mo, (a2) the corresponding CPD map measured by KPFM, and (a3) the histogram of the CPD map. (b1) Morphology of CVD Gr transferred on SiO₂, (b2) the corresponding CPD map measured by KPFM, and (b3) the histogram of the CPD map.
of the current peak appears due to decreased conductivity on the patches with increased thickness. The height and current profiles across one such patch (along the dashed lines indicated in Figs. 9(a) and 9(b)) are depicted in Fig. 9(d). As can be seen from these profiles, the current drops by several nA on the patch. In addition, small current drops (shown in Fig. S2 of Supplementary material) are visible along narrow Mo grain boundaries (imprinted in Gr as well) because of unstable contact with the AFM tip.

3.5.2. CVD Gr on SiO₂

As in the previous case for the electrical surface potential, a similar analysis of the current distribution was conducted for CVD Gr on SiO₂. The conductivity exhibits the same characteristics as previously observed for Gr on Mo: homogeneous and high current except on thicker patches (results presented in Fig. S3 of Supplementary material).

The small-scale images with topographic and current maps are presented for two cases: Figs. 10(a1) and 10(a2) for flat Gr (without patches) and Figs. 10(b1) and 10(b2) across a Gr patch. Both current images show homogeneous current despite of a dense network of Gr wrinkles. As we discussed above, wrinkles in the considered case have the geometry of simple, small and narrow ripples [20]. Then, during scanning in AFM contact mode, such wrinkles are pressed by the AFM tip leading to local Gr flattening, which finally gives a constant and high current. At the same time, Gr is wear resistive, so this local mechanical deformation does not result in Gr tearing. This is a significant improvement compared to CVD Gr grown on copper, where wrinkles are much wider and folded [20], leading to a more pronounced current drop. In the worst case, an AFM tip going across such wrinkles easily initiates local Gr tearing thus producing narrow and insulating trenches in a Gr sheet with zero current [23].

Still, the current map in Fig. 10(b2) contains local, point-like bumps. Therefore, one possible reason of decreased current on these parts is a less stable electrical contact between the AFM tip and Gr. Further improvement in the Gr growth process is needed in order to avoid these imperfections. Current histograms for both Gr with and without patches are given in Fig. 10(c). As can be seen, due to a slightly decreased conductivity of the domain with patches, the current peak is shifted by around 0.2 nA to a lower value.

4. Conclusion

In summary, we have demonstrated that although few-layer Gr grown on Mo does contain wrinkles with a height of several nanometers, the wrinkles are much narrower than in CVD Gr grown on copper, and they do not have a detrimental effect on uniformity of wear and electrical properties. It is shown that few-layer Gr grown by CVD on sputtered Mo films is characterized with a very low friction coefficient of around 0.13. Its wear resistance is improved compared to CVD Gr grown on copper, giving the threshold normal load for wear of around 4 μN. The considered Gr has very uniform surface potential over large areas, with RMS variability on the order of 5 mV for areas as large as 50 × 50 μm². The uniformity of electrical properties is better than in other types of Gr and is on par with industrial-grade materials such as...
silicon and metals deposited by atomic layer deposition. The local conductivity of the Gr films is also uniform, although with small variations at the edges of Gr patches with varying thickness. The patches are a result of the growth process which should be further optimized in order to overcome this issue.

We thus propose that few-layer Gr grown on Mo holds strong potential for use as an ultrathin solid lubricant for friction and wear reduction. It can also be used as an ultrathin electrode in integrated electronics, allowing wafer-scale device uniformity and reproducibility. Furthermore, the material holds potential as a substrate for self-assembly and for other uses that require uniform and well-defined electrical properties over large areas.
