Abstract

In pursuit of better accuracy, higher speed and larger scale, manufacturers of high-performance devices increasingly rely on components which have been designed with a multidisciplinary approach from the outset. In the context of motion systems, this means that for instance structural mechanics, control engineering and thermal analysis are considered early in the design. In addition, the prospect of producing freeform device components using additive manufacturing at full scale allows designers to even further refine components to a specific purpose, or even integrate multiple functions into a single component. The design freedom offered by additive manufacturing is far greater than that offered by traditional techniques. To exploit this freedom a topology optimization framework is proposed that allows to determine the optimal material quantity and distribution within a design volume. In particular, this article focuses on the closed-loop control performance of a motion system component, while simultaneously ensuring that mechanical requirements are met. Based on an example, it is demonstrated that this leads to nontrivial and non-intuitive designs which provide improved performance at lower structural mass compared to eigenfrequency designs. The framework allows rapid development of prototype designs, which may eliminate some of the costly design iterations which are currently made in industrial practice.

1. Introduction

The next generation of high-performance devices relies on components which have been designed with a multidisciplinary approach from the outset [1, 2]. In the context of motion systems, this means that for instance structural mechanics, control engineering and thermal analysis are already considered in the initial design. Tight demands on precision, scale and speed have made this timely multidisciplinary approach a necessity, since later on in the design process unfavorable characteristics of the design may have become hard to rectify. Furthermore, recent developments in additive manufacturing allow refining components even further by placing material only where it is functional. The design freedom offered by additive manufacturing is far greater than that offered by traditional techniques. To exploit this freedom a topology optimization framework is proposed that allows to determine the optimal material distribution within a design volume. Topology optimization [3] is already established as a design tool in, e.g., the aerospace and automotive industries, where it is mostly used to optimize components for minimal mass subject to strength and

12 stiffness requirements. Nevertheless, significant developments are required to bring these techniques to a level where
13 industry can apply them to complex multidisciplinary design problems with more sophisticated performance metrics.

14 For controlled flexible structures it has long been recognized that it makes sense to design the structure and
15 controller simultaneously, rather than designing the controller as a second step [1, 2]. Hence, simultaneous design of
16 structures and controllers has received attention throughout the last three decades. Control design must necessarily
17 account for internal flexibilities in the cases of large-scale or high-precision systems. This was first explored for
18 large-scale spacecraft where the focus was often on analytical multivariable control techniques in combination with
19 discretely parameterized structures. The latter refers to structures with only a few design variables (sizes, cross-
20 sections) and truss structures. These optimal control frameworks optimize criteria in the time domain which relate
21 to actuator activity, kinetic energy and/or strain energy. Examples are found where these problems are solved using
22 gradient-based optimization [4, 5, 6, 7, 8, 9, 10, 11, 12, 13] and randomized algorithms [14, 15]. The latter do not
23 lend themselves to cases with many design parameters as they scale poorly [16].

24 A limitation of many of these approaches is that only a few structural parameters are considered, allowing limited
25 design freedom and certainly not topology design, which typically involves many thousands of design variables. A
26 further practical limitation of these efforts is that the considered control frameworks (LQ, LQR, etc...) have seen
27 very little application in industrial practice due to complexity and robustness issues. They are rarely used in the
28 frequency-domain control design practice for motion systems [1].

29 A few examples exist in literature in which topology optimization is coupled with control design [17, 18, 19, 20].
30 Silveira and Fonseca [20] propose the use of control performance a secondary objective. Zhu et al. [18, 19] propose a
31 nested optimization approach and also consider actuator placement is also considered. The controller is optimized in a
32 nested loop using standard tools, however no details are revealed as to how design gradient information was obtained
33 and whether this was done in a consistent manner. Accurate design gradient information is essential for efficient and
34 stable convergence in topology optimization [3].

35 To develop a feasible approach which simultaneously incorporates controller and topology design, this article
36 focuses on a rather simple controller framework. Use is made of static (rigid-body) decoupling of the system in com-
37 bination with independent, fixed-structure PID controllers [21]. In fact, this is a fairly standard approach for motion
38 systems. Instead, complexity in terms of design freedom is offered by coupling the framework to topology optimiza-
39 tion, which provides great freedom with regards to the material distribution [3], making it a natural counterpart to
40 additive manufacturing. A frequency-domain approach to the integrated design of control system and structure was
41 previously developed in [22] and to the best of our knowledge that was the first attempt in literature. Recent years
42 have seen an increased interest in integrated optimization in the field of mechatronics [23, 24], but no systematic
43 approaches are available for joint topology and frequency-domain controller optimization.

44 A heuristic that could be used for motion systems is to design structures for maximum natural frequencies [25, 26].
45 From the point of view of control design these should usually be as high as possible. This criterion by itself, however,
46 does not convey any information about mode *shapes* and their effects on the frequency response functions seen by
47 the controller. Therefore, this approach may lead to conservative or poorly balanced designs because determining the
48 relevant modes a priori is very hard.

49 It is unlikely that optimizing for closed-loop performance alone will completely define a mechanical design,
50 since it only involves the dynamical behavior between actuators and sensors. This situation may be improved by
51 distinguishing between point of control (e.g., a sensor) and point of interest (e.g., location on a substrate), but it is
52 likely the case that other mechanical requirements must be taken into account to fully define the design. Thus, it makes
53 sense to include most other mechanical requirements from the start, since the design needs to satisfy them anyway.

54 This article considers the topology design of a high-precision motion stage with three degrees of freedom. There is
55 a strong link between the dynamics of the stage and the achievable closed-loop performance (such as bandwidth) and
56 the stage cannot be modelled as a rigid body. A topology optimization formulation is developed which directly designs
57 for closed-loop performance (based on first ideas discussed in [22]) subject to closed-loop stability requirements. The
58 stage is simultaneously required to satisfy stiffness requirements with regards to the deformations that occur during
59 motions and accelerations. A final important consideration is that the dependence of the dynamics on the operating
60 point is taken into account: depending on the position of the stage, the sensor locations change and thereby the
61 observed dynamics.

62 Compared to our previous work in [22], which was restricted to a single-input-single-output system with only one
63 control loop and 2 control parameters, now multiple-input-multiple-output (MIMO) systems with rigid-body decou-

Figure 1: Simplified representation of a free-floating motion stage which can be controlled in three planar degrees of freedom (DoF). Each of the two sensors measures x and y displacements. Two actuators are available in each of the x and y directions to provide 3-DoF controllability. The light gray area may be modified by topology optimization.

64 pling and several control loops are considered. Also, the design process is set-up so that the control system functions
 65 when the sensor location changes. Finally, mechanical requirements on the design are added in this framework.

66 Next to presenting an integrated topology optimization formulation, the main contributions of this article comprise
 67 systematic and consistent design sensitivity analysis, which is crucial to the success of gradient-based optimization.
 68 This involves:

- 69 • Design sensitivity analysis of reduced order modal models of detailed finite element models;
- 70 • Design sensitivity analysis of metrics related to closed-loop MIMO transfer functions;
- 71 • Design sensitivity analysis of the response to static and self-equilibrated loads;
- 72 • Actuator masses which scale with the mass of the overall design;
- 73 • Control design which is robust against varying sensor locations;
- 74 • Design-dependent static decoupling of rigid-body motions.

75 In this article all these aspects are incorporated into a single optimization framework to address realistic problems.

76 1.1. Outline and guide to readers

77 Sections 2 and 3 describe the modelling and optimization procedure and are sufficient to comprehend the essential
 78 ideas behind the methodology and the case study in Sec. 5. The interested reader can (selectively) consult Sec. 4,
 79 which presents in more detail the design sensitivity analysis which is at the heart of the optimization framework.

80 2. Setup and modelling

81 A simplified 2D model of a positioning stage is considered, as shown in Fig. 1. This model represents a component
 82 in a precision device and is treated as a flexible body, suspended and positioned by actuator forces F_x and F_y . The
 83 forces F_x always act simultaneously, whereas $F_{y,1}$ and $F_{y,2}$ can be applied separately, leading to three independent
 84 force inputs. Furthermore, there is a contactless measurement setup. It is assumed that the coordinate x is measured
 85 as the average between the two sensors, whereas the coordinates y_1 and y_2 are measured independently. Thus, there
 86 are also three independent measurements. Together, the inputs and outputs allow positioning of the stage in any
 87 of the three rigid-body degrees of freedom (defined as x , y and θ , cf. Fig. 1) and allow unique measurement of this
 88 position. Note that depending on the position of the stage with respect to the metrology frame, the sensors see different
 89 points on the substrate, giving rise to *position-dependent dynamics* (see Secs. 2.1 and 3). Within a particular control
 90 task, however, the stage can be considered to be at a fixed x -position as far as the position-dependent dynamics

91 are concerned (small motion ranges about a given position are assumed), so that the local dynamics are linear and
92 time-invariant.

93 Each of the actuators is defined by a mass associated to the dark gray areas in the diagram. The mass of each
94 actuator depends upon the total mass of the stage (see Sec. 2.7), as a result of actuator scaling to achieve the desired
95 accelerations. Finally, there is a substrate layer which has different material properties.

96 2.1. Mechanical modelling

The system is modelled using a finite element (FE) discretization. It is assumed that the actuator forces are uniformly distributed throughout the actuator bodies. Mathematically, the dynamics can be written as:

$$M(\theta)\ddot{x} + K(\theta)x = B\tilde{u}, \quad (1a)$$

$$\tilde{y} = Cx, \quad (1b)$$

97 in which $M(\theta)$ and $K(\theta)$ are the mass and stiffness matrices which depend on the design θ , x is the vector of nodal
98 displacements, B is a collection of 3 normalized actuation vectors corresponding to 1 N of actuator force, $\tilde{u} \in \mathbb{R}^{n_u}$
99 contains the inputs (forces), C is a matrix of 3 normalized sensing vectors and $\tilde{y} \in \mathbb{R}^{n_y}$ is a vector of outputs. Note that
100 C is itself a function of the stage x -position, due to the relative motion between the stage and the metrology frame.

The dynamic behavior of the stage is approximated by a reduced-order model which is based on the first n modes of the structure (including the rigid-body modes), using a mode truncation approach. These dynamics can be written as:

$$\ddot{\eta} + 2Z\Omega\dot{\eta} + \Omega^2\eta = \Phi^T B\tilde{u}, \quad (2a)$$

$$\tilde{y} = C\Phi\eta. \quad (2b)$$

The matrices have the following structure:

$$\Omega = \text{diag}(\omega_1, \omega_2, \dots, \omega_n),$$

$$\Phi = [\phi_1 \ \phi_2 \ \dots \ \phi_n],$$

$$Z = \text{diag}(\zeta_1, \zeta_2, \dots, \zeta_n),$$

in which (ω_i, ϕ_i) is the i -th eigenpair and ζ_i is the corresponding modal damping. Note that modal damping has been introduced, which is common in the modelling of high-performance mechatronic systems [1]. Damping ratios of 0.5% are assumed in this work. The transfer function related to this model (the Laplace transform of (2)) is denoted by $P(s)$:

$$P(s) = C\Phi(s^2I + 2Z\Omega s + \Omega^2)^{-1}\Phi^T B. \quad (3)$$

101 2.2. Rigid-body decoupling

Static decoupling of rigid-body motions is obtained by computing pre and post compensation matrices $W_A \in \mathbb{R}^{n_u \times n_u}$ and $W_S \in \mathbb{R}^{n_y \times n_y}$ [21] to result in a statically decoupled plant $G(s)$:

$$G(s) = W_S P(s) W_A. \quad (4)$$

102 This means that the compensated system has a new set of input and output signals $u = [F_u \ F_y \ F_\theta]$ and $y =$
103 $[x \ y \ \theta]^1$, for which it holds that a constant input to each of the inputs gives a constant rigid-body acceleration,
104 which affects only the corresponding output. The advantage is that this makes it possible to design independent
105 single-input-single-output (SISO) controllers thanks to limited interaction between the control loops.

¹For simplicity it is assumed that the system is neither under nor over-actuated regarding rigid-body motions, such that W_A and W_S are square and unique.

Considering only rigid-body modes Φ_r and using (2), equation (4) can be rewritten as:

$$\begin{aligned}\ddot{x} &= \Phi_r \Phi_r^T B W_A u, \\ \ddot{y} &= W_S C \Phi_r \Phi_r^T B W_A u\end{aligned}$$

Then, two conditions are imposed. First, the independent inputs should only activate independent user-defined motions Φ_d^2 as seen from the outputs, expressed by $C\ddot{x} \equiv C\Phi_d u$. This leads to:

$$W_A = (C\Phi_r \Phi_r^T B)^{-1} C\Phi_d. \quad (5)$$

Second, a normalization condition is imposed such that the compensated rigid-body system behaves as a unit mass with an identity inertia tensor, independent of the design. This simplifies controller tuning and is expressed as $\lim_{s \rightarrow 0} s^2 G(s) = I$, which ultimately leads to:

$$W_S = (C\Phi_d)^{-1}.$$

106 2.3. Controller

In this article the focus is not on exploring state-of-the-art controller synthesis procedures. Rather, the focus is on combining topology optimization and controller tuning into a single framework. Hence, a simple but industry-standard control configuration is chosen, in which each rigid-body motion $G_{ii}(s)$ is controlled by a PID controller of the following type (Fig. 2):

$$C_i(s; k, \omega_b) = k \frac{s + \frac{1}{5}\omega_b}{s} \frac{3s + \omega_b}{s + 3\omega_b} \frac{5\omega_b}{s + 5\omega_b}. \quad (6)$$

107 This controller structure is often applied in the field of motion systems [27, 1] (e.g., systems with a double integrator)
108 and provides integral action up to $\frac{1}{5}\omega_b$, phase lead between $\frac{1}{3}\omega_b$ and $3\omega_b$ and first order roll-off beyond $5\omega_b$ (Fig. 3).
109 This leads to sufficient phase lead in the crossover region, low frequency disturbance rejection and limited high-
110 frequency control action.

111 Note that the methodology described in this article is not limited to the PID control scheme described here, but in
112 principle can treat any parameterized and differentiable controller which has a frequency-domain representation.

113 For purposes of optimization the controller parameters k and ω_b are scaled such that their expected ranges lie
114 approximately between 0 and 1.

115 2.4. Closed-loop performance and constraints

The closed-loop disturbance sensitivity function is defined as [28, 21]:

$$S(s; \theta) = [I + L(s; \theta)]^{-1}, \quad (7)$$

² Φ_d is further defined in Sec. 4.1.1, but usually contains intuitive unit rigid-body motions such as uniform x and y translation and rotation about the z -axis.

Figure 2: Closed-loop configuration of one of the statically decoupled control loops. The output y_i is regulated to track a reference signal r_i . The controller uses the error signal e_i and compensates tracking errors due to disturbance signal d_i by generating a control signal u_i .

Figure 3: Frequency response of the PID controller (6) for $k = 1$ and $\omega_b = 100$ Hz. The dashed lines indicate the frequencies $\frac{1}{5}\omega_b$, $\frac{1}{3}\omega_b$, $3\omega_b$ and $5\omega_b$.

116 in which L is the loop transfer function $L = GC$. Also, the dependence upon controller parameters and structural
 117 parameters, gathered in the vector θ , has been made explicit. The sensitivity function is an n_y -by- n_y transfer function
 118 matrix, and in this article the focus is on the diagonal elements. As described in Sec. 2.2, the plant P has been
 119 converted to a statically decoupled plant G . In that case the diagonal elements of $S(s; \theta)$ describe the sensitivity of
 120 each of the rigid-body motions to a perturbation of the same motion. Cross-sensitivities have not been considered,
 121 but an important consideration when examining cross-sensitivities is that these are not necessarily dimensionless and
 122 normalised, a fact which holds by definition for the diagonal components.

123 Given the simple controller structure employed (see Sec. 2.3), the diagonal elements of the sensitivity function
 124 will have a magnitude response which is similar to Fig. 4. The low-frequency asymptotic behavior, with a 60 dB/decade
 125 slope, motivates the use of a single frequency as performance indicator. That is, the magnitude at a single frequency,
 126 say 10 Hz, will be indicative of performance (i.e., rejection of output disturbances) across the low-frequency range.

127 In SISO controller design, a sensitivity function which does not exceed an amplification of 6 dB implies that the
 128 loop gain remains outside the hatched circle in the Nyquist plot of the loop gain (see Fig. 5) [28] and implies a gain
 129 margin $GM \geq 6 \text{ dB}$ and a phase margin $PM \geq 29^\circ$ [21]³. This still holds if each controller is tuned with the other
 130 loops closed.

131 A baseline configuration is created using a sequential loop closure approach [21], in which controllers are sequen-
 132 tially designed for the three rigid-body motions, based on the initial dynamics of the stage. It is important to realise
 133 that subsequently, during optimization, the controllers are simultaneously updated and the performance in all three
 134 loops is evaluated simultaneously. In that sense the procedure is more favourable than a sequential redesign, since
 135 each of the loops is tuned in the presence of the other control loops (all loops remain closed). This also means that the
 136 influence of each controller's parameters on the performance and constraints in all the other loops is accounted for.

137 2.4.1. Performance

The scalar performance function is a weighted combination of the magnitudes on the diagonal of S , i.e.:

$$f_0(\theta) = \sum_{i=1}^{n_y} w_i |S_{ii}(j\omega^*; \theta)|_{\text{dB}}, \quad (8)$$

138 in which w_i is a weight attached to the i -th control loop and ω^* denotes the frequency at which the performance is eval-
 139 uated. The notation $|\cdot|_{\text{dB}} = 20 \log_{10} |\cdot|$ refers to the complex modulus converted to decibels, usually a negative value.
 140 Decibels are used to accommodate the potentially large dynamic range of $|S_{ii}(j\omega^*; \theta)|$. Each component $|S_{ii}(j\omega^*; \theta)|_{\text{dB}}$
 141 may have a rather different initial value, so that a reasonable initial choice is to take w_i equal to the reciprocal of

³Except in special cases, see [29].

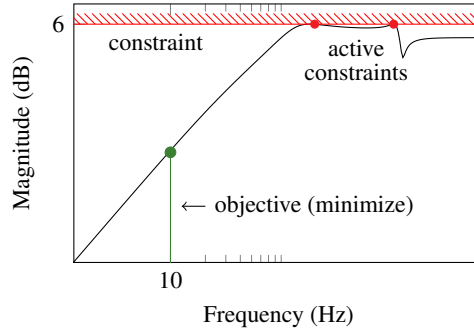

Figure 4: Typical shape of the disturbance sensitivity for one control loop. Attenuation is optimized at 10 Hz and amplification must remain below 6 dB everywhere.

142 $\|S_{ii}(s^*; \theta_0)\|_{\text{dB}}$ for the initial design θ_0 . In that way, $f_0(\theta_0)$ sums to n_y for the initial parameter set and each sensitivity
 143 contributes equally to the objective in a relative sense.

144 While the disturbance sensitivity has been used here as a specific example of a performance measure, any open
 145 or closed-loop transfer function, or a combination of those, could be used. This means that a wide range of problems
 146 can be addressed using the generic methodology presented here, as long as a limited number of frequencies (in this
 147 case only ω^*) needs to be considered.

148 2.4.2. Constraints

For each diagonal element of $S(s)$, the constraint $|S_{ii}(j\omega)| \leq S_{\max}$ is enforced (often $S_{\max}^{\text{dB}} = 6$ dB). To achieve
 this, the frequency response is scanned for all peaks (using the method described in [30]) and each of these peaks
 is monitored. The largest possible number of peaks in a sensitivity frequency response is related to the number of
 modes. Each of these constraints can be formulated as:

$$f_c(\theta) = |S_{ii}(j\omega_k; \theta)|_{\text{dB}} \leq S_{\max}^{\text{dB}}, \quad \begin{array}{l} i = 1, \dots, n_y \\ k = 1, \dots, n_f^i \end{array} \quad (9)$$

149 in which n_f^i is the number of peaks detected in the i -th sensitivity function and ω_k is the frequency at which a peak
 150 occurs.

151 Note that as the design (i.e., θ) changes and the optimization proceeds, the number of peaks in each transfer
 152 function may change. Hence, the set of constraints (9) can be a set which changes in size. This also means that these
 153 constraints are not globally continuously differentiable. Still, the local gradient gives information on feasible design
 154 changes.

A further constraint is that all closed-loop eigenvalues should be in the open left-half plane. Assume that state-
 space realizations of the reduced-order decoupled system (4) as well as the combined controllers (6) are given as:

$$G(s) : \begin{cases} \dot{x} = Ax + Bu \\ y = Cx \end{cases} \quad C(s) : \begin{cases} \dot{x}_c = A_c x_c + B_c y \\ u = C_c x_c \end{cases}$$

It can be shown that the closed-loop system matrix for a unity negative feedback loop between $G(s)$ and $C(s)$ satisfies:

$$\Psi = \begin{bmatrix} A & BC_c \\ -B_c C & A_c \end{bmatrix}. \quad (10)$$

All eigenvalues of this matrix must have negative real parts, which can be expressed as a further constraint:

$$f_\lambda(\theta) = \psi_{\max}^p(\text{Re}\{\lambda_i(\Psi)\}) < 0, \quad i = 1, \dots, n_\lambda. \quad (11)$$

155 In this equation $\psi_{\max}^p(\cdot)$ denotes a smooth approximation to the maximum function (to be defined in Sec. 4.6) [31,
 156 32], which is used in order to aggregate individual eigenvalue constraints into a single constraint imposed upon the
 157 (approximate) largest eigenvalue.

Figure 5: A typical Nyquist plot of a control system showing $L(j\omega)$, the critical point $(-1, 0)$ and the region $|S(j\omega)| > S_{\max}$.

158 2.5. Mechanical requirements

159 Since the stage is used for very precise positioning, it must meet several mechanical stiffness requirements in
 160 addition to providing optimized closed-loop positioning performance at the points of control (i.e., the measurement
 161 locations).

To achieve peak uniform acceleration \ddot{x}_u of the stage, certain (design-dependent) actuator forces $f_{\text{accel}}(\theta)$ are applied which are in equilibrium with the inertia forces of the accelerating stage according to d'Alembert's principle. This causes a static deformation of the stage. Under these conditions the shear stress between the stage and the substrate may not exceed a certain level to avoid damage. This constraint can be formulated as:

$$f_{\sigma}(\theta) = \psi_{\max}^p(\sigma_i(\theta)) \leq \sigma_{\max}, \quad i \in \mathcal{I} \quad (12a)$$

$$\sigma(\theta) = Dx(\theta), \quad (12b)$$

$$K(\theta)x(\theta) = f_{\text{accel}}(\theta) - M(\theta)\ddot{x}_u, \quad (12c)$$

162 in which D is a matrix which computes the shear stress values at all the nodes and \mathcal{I} is the set of nodes along the
 163 interface between the stage and the substrate. Note that the right hand side of (12c) must be self-equilibrated such
 164 that no rigid-body motions are induced. Further, $\psi_{\max}^p(\cdot)$ is the same aggregation function used for the eigenvalue
 165 constraints (11) in order to combine all stress constraints into a single constraint.

Similarly, certain external disturbance forces f_{dist} act on the stage. These disturbances are counteracted with corrective actuator forces $f_{\text{corr}}(\theta)$ by the control system. Under the influence of these combined forces, the stage deforms. These deformations may not allow any point on the substrate to displace by more than a set amount. Such constraints can be expressed as:

$$f_x(\theta) = \psi_{\max}^p(\delta x_i(\theta)) \leq \delta x_{\max}, \quad i \in \mathcal{K} \quad (13a)$$

$$K(\theta)x(\theta) = f_{\text{corr}}(\theta) + f_{\text{dist}}, \quad (13b)$$

166 in which \mathcal{K} is a set of degree-of-freedom indices. Here too, the right hand side of (13b) must be self-equilibrated.

167 2.6. Topology parameterization

The structure is parameterized using the density approach in topology optimization [3]. This implies that each finite element is assigned a design value ρ_e between ρ_e^{\min} and 1 (see Fig. 1). Note that $\rho_e^{\min} > 0$ in order to avoid a singular stiffness matrix (cf. (14a)). Then, the properties of that element are scaled with the design value according to an interpolation function. A modified form of the SIMP (Solid Isotropic Material with Penalization) approach is used, which is widely used in topology optimization [3]. Specifically, for an element e , this results in:

$$K_e = \rho_e^3 K_e^{(0)}, \quad (14a)$$

$$M_e = \begin{cases} \rho_e M_e^{(0)}, & \rho_e > 0.1, \\ \rho_e^5 M_e^{(0)}, & \rho_e \leq 0.1, \end{cases} \quad (14b)$$

168 in which $K_e^{(0)}$ and $M_e^{(0)}$ are the element stiffness and mass matrices for solid material. These interpolations ensure
 169 that intermediate-density elements tend to underperform (i.e., for most intermediate density values the stiffness is far
 170 lower than the mass), encouraging a black-and-white design. The special mass interpolation (14b) ensures that for low
 171 design values the element mass tends to zero faster than its stiffness. This is necessary to suppress localized vibration
 172 modes in low-density areas [25, 33, 34, 22].

The element matrices are assembled into the global finite element matrices K and M according to [35]:

$$K = \mathbf{A}_{e=1}^{n_e} K_e, \quad M = \mathbf{A}_{e=1}^{n_e} M_e, \quad (15)$$

173 with the assembly operator performing the scattering of element matrices to the global degrees of freedom.

A spatial filter is applied to the design values to prevent mesh-dependent solutions, to avoid so-called “checker-boarding”, and to introduce a minimum length scale [36, 37]. The filter is defined as

$$\tilde{\rho}_e = \frac{\sum_{k=1}^{n_e} w_{ek} \rho_k}{\sum_{k=1}^{n_e} w_{ek}}, \quad w_{ek} = \max(0, r_{\min} - \text{dist}(k, e)).$$

Hence, the design values $\tilde{\rho}_e$ becomes a distance-weighted average of itself and its nearest neighbors. The *filtered design values* $\tilde{\rho}_e$ replace the *design values* ρ_e in (14a–14b). It is useful to note that the global filtering operation can be written and implemented as:

$$\tilde{\rho} = F\rho, \quad (16)$$

174 in which F is a sparse matrix.

175 Referring to the diagram (Fig. 1), only the light gray areas have been parameterized, which implies that only the
 176 topology in these areas may be modified.

177 2.7. Design-dependent actuator masses

The actuators shown in Fig. 1 are assumed to be of the electromagnetic type. It is assumed that the mass of each of these actuators can be expressed as a fraction of the overall structural mass, since accelerating a heavier stage will require larger actuators. Specifically, the mass of an actuator a can be expressed as:

$$m_a(\theta) = \mu_a m_c(\theta),$$

178 in which $m_c(\theta)$ is the total mass of the component excluding all actuators and μ_a is the mass fraction⁴ of the actuator.
 179 Design-dependent actuator masses are expected to have a significant influence on the dynamic behavior of the stage.

180 3. Optimization problem formulation

181 At this point it is useful to recall the goal of this article, which is to develop a procedure to optimize the closed-loop
 182 performance (defined in Sec. 2.4.1) of a motion system, subject to constraints and mechanical requirements on the
 183 structure (defined in Secs. 2.4.2 and 2.5). To this end, a gradient-based optimization algorithm is used, which makes
 184 use of the objective and constraint values and their gradients. The computation of these design gradients is discussed
 185 in the next section, Sec. 4. Fig. 6 shows the outline of the initialization and optimization process.

186 Use is made of sequential quadratic programming (SQP), following the ideas in [38, 39]. A fairly conservative
 187 optimization strategy was chosen, in order to reduce the likelihood of ending up in an infeasible design (meaning that
 188 the combination of the structure and the controller is unstable) from which it is hard to recover. The chosen SQP
 189 algorithm makes use of the objective and constraint function values and their gradients with respect to the parameters.
 190 Second order gradient information is not computed, but estimated by means of a reciprocal intervening variable
 191 approach [38, 39].

⁴These mass fractions can usually be estimated from actuator force density data or empirical data.

192 All design variables are collected in a vector θ , which then consists of the topology design variables ρ_e , $e =$
 193 $1, \dots, n_d$ and the controller variables $k_i, \omega_{b,i}$, $i = 1, \dots, n_c$. Obviously, the topology parameters ρ_e affect the closed-
 194 loop performance and stability as well as the mechanical constraints via the mass and stiffness matrices. The controller
 195 parameters on the other hand only affect closed-loop performance and stability.

The optimization problem is formulated as:

$$\begin{aligned} & \underset{\theta}{\text{minimize}} && \max_{x \in \mathcal{X}} f_0(\theta, x) \\ & \text{subject to} && f_i(\theta, x) \leq f_i^{\max} \quad \forall \quad i = 1, \dots, n_c, \\ & && x \in \mathcal{X}. \end{aligned} \quad (17)$$

196 In this problem $f_0(\theta, x)$ is the scalar objective function (8) and $f_i(\theta, x)$ are the, possibly vector-valued, constraints.

197 Note that in the objective and constraints a parameter x has been introduced. The dynamics seen by the control
 198 system depend on the sensor positions as the stage moves with respect to the metrology frame. To account for this
 199 fact, the design is performed simultaneously for multiple positions $x \in \mathcal{X}$, where \mathcal{X} is a set of locations.

200 In the examples in this article three x -locations are considered: the center position and the extreme left/right
 201 positions of the stage. In each design iteration the worst case performance out of three sensor locations is optimized,
 202 while ensuring that the constraints are simultaneously satisfied for each of the three locations, effectively leading to a
 203 robust design.

204 3.1. Optimization problem convergence and uniqueness

205 Due to the non-linear and non-convex nature of the objective function and the constraint functions and the use of
 206 a gradient-based optimization algorithm, the existence and uniqueness of a global solution is not guaranteed. This is
 207 commonly accepted in topology optimization [3, 16]. A requirement of the proposed procedure is that one starts with
 208 a feasible design. This means that the starting combination of the topology (the structural lay-out) and the controller
 209 should satisfy the constraints and have a reasonable closed-loop performance, given the structural dynamics. This can
 210 be achieved by manually tuning the controller to the initial structural design. From this starting point onwards, the
 211 gradient-based search will attempt to improve the performance subject to the constraints. The optimization process
 212 may be terminated when the relative change in the objective value becomes small, or a finite number of iterations has
 213 been performed.

214 4. Design sensitivity analysis

215 The optimization framework presented in this article relies heavily upon the ability to efficiently compute design
 216 sensitivity information. First, for a given design, say the initial topology with initial controller parameters defined by
 217 θ_0 , the performance and all constraint functions are computed. Then, the gradients of these functions with respect to
 218 all design variables θ are computed.

219 Although finite-differencing is a simple technique to obtain sensitivity information, the number of design variables
 220 (in particular the structural design variables) is very significant and can range into the millions for detailed finite
 221 element meshes, making finite-differencing infeasible. Since this number is large in comparison with the number of
 222 objective and constraint functions, use is made of adjoint sensitivity analysis where possible.

223 The following subsections treat the sensitivity analysis of the various analysis components which constitute the
 224 closed-loop and mechanical analysis of the design problem.

225 4.1. Mode sensitivities

The reduced-order system model (3) is based on the natural frequencies and eigenmodes of the system. Hence,
 the sensitivity of the reduced order model depends on the sensitivities of the modes themselves. This section de-
 scribes how eigenvector and eigenvalue sensitivities are computed using an adjoint method according to [40, 41]. The
 eigenvalue problem related to the dynamics (1) is:

$$(K - \omega_i^2 M)\phi_i = 0, \quad \phi_i^T M \phi_i = 1.$$

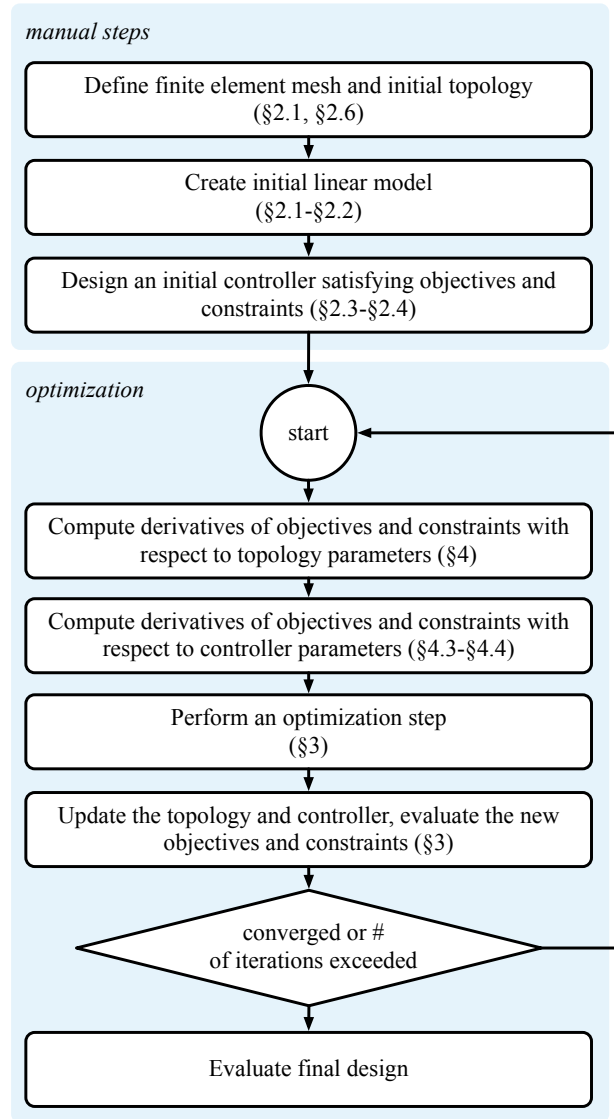

Figure 6: Flowchart outlining the steps in the algorithm.

Only the sensitivities of certain linear combinations of the modes are computed. This can be expressed as:

$$\tilde{\phi}_i = P^T \phi_i, \quad (18)$$

226 in which P computes certain linear combinations of the DoFs of interest (for instance based on the locations where
227 a load is applied or where a displacement is measured). In the simplest case, P could be a vector which selects one
228 element from ϕ_i .

Next, (18) is augmented with Lagrange multipliers to perform adjoint sensitivity analysis:

$$\tilde{\phi}_i^* = P^T \phi_i + \mathcal{M}_i^T (K - \omega_i^2 M) \phi_i + \nu_i \left(\frac{1}{2} - \frac{1}{2} \phi_i^T M \phi_i \right).$$

\mathcal{M}_i and ν_i are arbitrary but non-zero matrix-valued and vector-valued Lagrange multipliers, respectively, both related

to the i -th mode. Computing the gradient leads to:

$$\frac{d\tilde{\phi}_i^*}{d\theta_j} = P^T \frac{d\phi_i}{d\theta_j} + \mathcal{M}_i^T \left(\frac{dK}{d\theta_j} - \omega_i^2 \frac{dM}{d\theta_j} - \frac{d\omega_i^2}{d\theta_j} M \right) \phi_i + \mathcal{M}_i^T (K - \omega_i^2 M) \frac{d\phi_i}{d\theta_j} + v_i \left(-\frac{1}{2} \phi_i^T \frac{dM}{d\theta_j} \phi_i - \phi_i^T M \frac{d\phi_i}{d\theta_j} \right). \quad (19)$$

Gathering all terms involving $\frac{d\phi_i}{d\theta_j}$ and $\frac{d\omega_i^2}{d\theta_j}$ the following adjoint equation can be defined:

$$\begin{bmatrix} K - \omega_i^2 M & -M\phi_i \\ -\phi_i^T M & 0 \end{bmatrix} \begin{bmatrix} \mathcal{M}_i \\ v_i^T \end{bmatrix} = \begin{bmatrix} -P \\ 0 \end{bmatrix}. \quad (20)$$

Given this choice, what remains from (19) is:

$$\frac{d\tilde{\phi}_i}{d\theta_j} = \mathcal{M}_i^T \left(\frac{dK}{d\theta_j} - \omega_i^2 \frac{dM}{d\theta_j} \right) \phi_i - v_i \frac{1}{2} \phi_i^T \frac{dM}{d\theta_j} \phi_i. \quad (21)$$

229 Hence, for each mode i , (20) must be solved once, after which (21) can be used to compute sensitivities of $\tilde{\phi}_i$ with
230 respect to each design variable θ_j .

The sensitivity of the eigenvalue ω_i^2 can be computed using [3]:

$$\frac{d\omega_i^2}{d\theta_j} = \phi_i^T \left(\frac{dK}{d\theta_j} - \omega_i^2 \frac{dM}{d\theta_j} \right) \phi_i. \quad (22)$$

231 Note that the sensitivity expressions for mode shapes and natural frequencies in this subsection are only valid for
232 modes which have multiplicity one. For modes with multiplicity greater than one⁵, one must resort to specialized
233 techniques [42, 43].

234 4.1.1. Sensitivity analysis of rigid-body modes

Rigid-body modes can usually be defined by physical reasoning. I.e., for a free 3D structure one may define 3 translations along the coordinate axes and 3 rotations about these axes, for instance about the center of mass. However, unless the body has three axes of symmetry and a diagonal inertia tensor, these modes will *not* be mass-orthogonal. Assume that such “intuitive” modes have been computed and collected in the matrix Φ_d , then a non-unique transformation matrix T can be computed which makes these modes mass-orthonormal, by requiring:

$$\Phi_{d,m} T = \Phi_d, \quad (23)$$

such that:

$$\Phi_{d,m}^T M \Phi_{d,m} = T^{-T} \Phi_d^T M \Phi_d T^{-1} = I,$$

or $\Phi_d^T M \Phi_d = T^T T$. One admissible T can be found by requiring T to be symmetric, such that:

$$\Phi_d^T M \Phi_d = T^2, \quad (24)$$

in which T is the principal square root of $\Phi_d^T M \Phi_d$ [44]. The sensitivity of $\Phi_{d,m}$ follows by differentiating (23):

$$\frac{d\Phi_{d,m}}{d\theta_j} = -\Phi_d T^{-1} \frac{dT}{d\theta_j} T^{-1},$$

The sensitivity of the transformation matrix T follows by differentiating (24):

$$\Phi_d^T \frac{dM}{d\theta_j} \Phi_d = \frac{dT}{d\theta_j} T + T \frac{dT}{d\theta_j}.$$

235 which is a *continuous Lyapunov equation* that can be solved for $\frac{dT}{d\theta_j}$ using a range of techniques, for instance making
236 use of the Kronecker product [45, 46].

⁵This also occurs if there are multiple rigid-body modes, since these all have zero natural frequency, cf. Sec. 4.1.1.

237 **4.2. Sensitivity of the decoupled plant G**

Making use of (3) and defining $\Sigma = s^2I + 2Z\Omega s + \Omega^2$, the gradient of $P(s)$ can be computed:

$$\frac{dP(s)}{d\theta_j} = C \left(\frac{d\Phi}{d\theta_j} \Sigma^{-1} \Phi^T - \Phi \Sigma^{-1} \frac{d\Sigma}{d\theta_j} \Sigma^{-1} \Phi^T + \Phi \Sigma^{-1} \frac{d\Phi^T}{d\theta_j} \right) B,$$

with:

$$\frac{d\Sigma}{d\theta_j} = 2Z \frac{d\Omega}{d\theta_j} s + \frac{d\Omega^2}{d\theta_j}.$$

The sensitivity of the decoupled plant $G(s)$ then follows from the chain rule:

$$\frac{dG(s)}{d\theta_j} = W_S \frac{dP(s)}{d\theta_j} W_A + W_S P(s) \frac{dW_A}{d\theta_j}.$$

Note that W_S is design-independent. For W_A one finds the following design sensitivity from (5):

$$\frac{dW_A}{d\theta_j} = -(C\Phi\Phi^T B)^{-1} C \left(\frac{d\Phi}{d\theta_j} \Phi^T + \Phi \frac{d\Phi^T}{d\theta_j} \right) B W_A.$$

238 The sensitivities of the controllers with respect to the gain k and the bandwidth ω_b are readily obtained by dif-
 239 ferentiating (6), but could equally well be obtained by finite differencing due to the small number of parameters
 240 involved.

241 **4.3. Design sensitivity of closed-loop transfer functions**

242 It can be seen by inspection that in terms of sensitivity analysis both (8) and (9) require computation of the
 243 gradient of $|S_{ii}(j\omega)|_{\text{dB}}$ for a given frequency ω . These sensitivities are readily derived based on the results of the
 244 previous sections.

Since this article focuses on the sensitivity functions $|S_{ii}(j\omega)|_{\text{dB}}$, originally defined in (7), its design sensitivity will be derived as an example. However, the same principles can be applied to any other closed-loop function. For brevity the explicit dependencies of $S(s; \theta)$ on s and θ are dropped. Then, from (7) it follows that:

$$\frac{dS}{d\theta_j} = -S \left(\frac{dP}{d\theta_j} C + P \frac{dC}{d\theta_j} \right) S. \quad (25)$$

However, in most cases one is interested only in the complex modulus $|S_{kl}|$ of one element (k, l) of the matrix-valued sensitivity function, for which it is straightforward to show that:

$$\begin{aligned} \frac{d|S_{kl}|}{d\theta_j} &\equiv \frac{d}{d\theta_j} \sqrt{\mathcal{R}e\{S_{kl}\}^2 + \mathcal{I}m\{S_{kl}\}^2} \\ &= \frac{1}{|S_{kl}|} \mathcal{R}e \left\{ S_{kl}^* \frac{dS_{kl}}{d\theta_j} \right\}, \end{aligned}$$

245 in which the $*$ denotes complex conjugation. Note that the latter equation can be evaluated based on the result of (25).
 Finally, frequent use is made of values in decibels (cf. Sec. 2.4.1), for which the following relation is useful:

$$\frac{d|S_{kl}|_{\text{dB}}}{d\theta_j} = \frac{20}{\ln 10} \frac{1}{|S_{kl}|} \frac{d|S_{kl}|}{d\theta_j}.$$

246 **4.4. Sensitivity of closed-loop eigenvalues**

The eigenvalues λ_i and left and right eigenvectors $\phi_{i,l}$, $\phi_{i,r}$ of the closed-loop system matrix (10) are described by the equations:

$$\begin{aligned}\Psi\phi_{i,r} &= \lambda_i\phi_{i,r} \\ \phi_{i,l}^T\Psi &= \lambda_i\phi_{i,l}^T\end{aligned}$$

Sensitivities are found by differentiating the right-eigenvector problem according to the chain rule:

$$\frac{d\Psi}{d\theta_j}\phi_{i,r} + (\Psi - \lambda_i I)\frac{d\phi_{i,r}}{d\theta_j} - \frac{d\lambda_i}{d\theta_j}\phi_{i,r} = 0.$$

Pre-multiplying with the corresponding left-eigenvector and rearranging results in:

$$\frac{d\lambda_i}{d\theta_j} = \frac{\phi_{i,l}^T \frac{d\Psi}{d\theta_j} \phi_{i,r}}{\phi_{i,l}^T \phi_{i,r}}.$$

247 This equation allows one to compute the derivatives $\frac{d\lambda_i}{d\theta_j}$ of the closed-loop eigenvalues.

248 **4.5. Sensitivity analysis for mechanical constraints**

249 All mechanical constraints are of the form $f_i(x) - f_i^{\max} \leq 0$, in which x is the displacement field following from a
250 static finite element computation. For instance, $f_i(x)$ could describe the relative displacement between two points on
251 the structure, the absolute displacement of a set of points or the stresses at certain points. In each case, it is assumed
252 that $f_i(x)$ is a user-defined and continuously differentiable (vector) function of the deformation field x .

To efficiently compute the sensitivity of the constraint functions the adjoint method is used [3, 47]. This involves converting the function $f_i(x)$ to a Lagrangian which incorporates the constraints. In this case, the ‘‘constraints’’ are represented by the equilibrium equation $Kx = f$, with f the applied load corresponding to the case under consideration. The resulting expression is:

$$f_i^*(x) = f_i(x) + \lambda^T(Kx - f), \quad (26)$$

which implies that $f_i^*(x) = f_i(x)$ for any nonzero vector λ . Differentiating this expression with respect to a parameter θ_j yields:

$$\frac{df_i^*(x)}{d\theta_j} = \frac{\partial f_i(x)}{\partial \theta_j} + \frac{\partial f_i(x)}{\partial x^T} \frac{dx}{d\theta_j} + \lambda^T \left(\frac{dK}{d\theta_j} x + K \frac{dx}{d\theta_j} - \frac{df}{d\theta_j} \right). \quad (27)$$

The essence of the adjoint approach is to note that the term $\frac{dx}{d\theta_j}$ is expensive to evaluate. Hence, the freedom in choosing λ will be exploited to eliminate it from (27) by choosing:

$$K\lambda = \frac{\partial f_i(x)}{\partial x}. \quad (28)$$

Eq. (28) is the *adjoint equation* related to (26). With this choice of λ , (27) reduces to:

$$\frac{df_i^*(x)}{d\theta_j} = \frac{\partial f_i(x)}{\partial \theta_j} + \lambda^T \left(\frac{dK}{d\theta_j} x - \frac{df}{d\theta_j} \right). \quad (29)$$

253 Note that (29) is computationally relatively cheap to evaluate for each element θ_j of θ , mainly because (28) needs to
254 be solved only once.

255 4.6. Constraint aggregation

For some of the introduced constraints, like local displacement and stress constraints, it is not feasible to add each local constraint individually. In these cases, constraint aggregation is applied [31, 32]. The reasoning can be explained for the example of displacements: if each local displacement shall be less than an allowed value, the maximum of all local displacements must necessarily also be less than that value. Hence, the following implication holds:

$$\delta x_i < \delta x_{\max} \quad \forall i \implies \max_i \{\delta x_i\} < \delta x_{\max},$$

effectively allowing N constraints to be replaced by a single one. Since the maximum operator is non-differentiable, an approximation is introduced in the form of the Kreisselmeier-Steinhauser function [32]:

$$\psi_{\max}^p = \frac{1}{p} \ln \left(\sum_{i=1}^N e^{p x_i} \right).$$

This approximation is also continuously differentiable, leading to the approximate sensitivity:

$$\frac{d\psi_{\max}^p}{d\theta_j} = \frac{1}{\sum_{i=1}^N e^{p x_i}} \sum_{i=1}^N e^{p x_i} \frac{d x_i}{d\theta_j}.$$

256 See [32] for important aspects regarding the numerical implementation of this function.

257 4.7. Density filtering

Gradients of the mass and stiffness matrices can be computed with respect to the filtered design density field $\tilde{\rho}_e$ by making use of their definitions in (14) and (15), however, the relation to the actual design values ρ_e must be accounted for. Suppose a gradient $df_i/d\tilde{\rho}$ has been computed with respect to the entire design value vector ρ . Then, the following relation can be derived from (16):

$$\frac{d f_i}{d \rho} = F^T \frac{d f_i}{d \tilde{\rho}}.$$

258 4.8. Design-dependent actuator mass

259 Design-dependent actuator masses were discussed in Sec. 2.7. This section will show how such dependencies can
260 be incorporated into the sensitivity analysis.

It is assumed that the actuators are of a given geometry (i.e., the internal actuator topology is not parameterized and fixed) and that the element stiffness matrices in the parts therefore remain unaffected as the design proceeds. It is further assumed that the initial mass of an actuator equals m_a^0 . The mass fraction μ_a specifies that the part has a mass of μ_a times the mass of the component excluding all the actuators m_c . Using this information, each scaled element mass matrix within the part is computed according to:

$$M_e = \frac{\mu_a}{m_a^0} m_c M_e^0, \quad (30)$$

in which M_e^0 is the original element mass matrix. Further, note that m_c is defined as:

$$m_c = \sum_{e \in \mathcal{E}} \tilde{\rho}_e^p m_e^0, \quad (31)$$

261 in which p is the penalization coefficient according to (14b) and m_e is the unscaled mass of element e . Note that e
262 in the summation runs only over the component elements excluding actuators \mathcal{E} (i.e., does not include the elements
263 inside the actuators).

The sensitivity of (30) is then readily obtained as:

$$\frac{d M_e}{d \theta_j} = \left(\sum_{e \in \mathcal{E}} \frac{d \tilde{\rho}_e^p}{d \theta_j} m_e^0 \right) \frac{\mu_a}{m_a^0} M_e^0,$$

264 showing that the sensitivities of the element mass matrices within the actuators are related to the densities $\tilde{\rho}_e$ in a
265 straightforward way.

5. Case study

As an example design problem the 2D stage shown earlier in Fig. 1 is considered.

5.1. Problem definition and results

Optimization is performed according to (17). The objective function is composed of the disturbance attenuation at $\omega^* = 0.1$ Hz in each control loop, as given in (8). The total mass of the design is also added to the objective function with a small penalty factor (about 5% of the total objective value). The rationale behind this is that lighter designs are preferred, but the stimulus is small enough not to compromise the main objective of disturbance attenuation.

Furthermore, several constraints are imposed. For the control loops there are constraints on sensitivity function peaks (9) and on closed-loop stability (11). Mechanical constraints comprise constraints on shear stresses between the stage and the substrate (12) and deformations of the substrate (13).

The starting point for the optimization runs is a design in which the domain is filled with 75% density material (which corresponds to $E = 0.42E_0$ and $\rho = 0.95\rho_0$, following (14a-14b)) with $E_0 = 70$ GPa and $\rho_0 = 2700$ kg/m³ for the design area (aluminium) and $E_0 = 210$ GPa and $\rho_0 = 7000$ kg/m³ for the solid actuator areas (steel). To compare the integrated approach, an eigenfrequency optimization has also been performed. High natural frequencies are usually favourable for controller design. Hence, one can maximize certain eigenfrequencies of the stage, while still imposing the same set of mechanical design constraints and adding the same mass penalty. A certain spacing between eigenfrequencies is also desirable from a control perspective. Several problem formulations for eigenfrequency design are possible, for instance:

1. Maximize f_1 subject to $f_2 \geq 1.1f_1$;
2. Maximize f_1 subject to $f_2 \geq 1.1f_1$ and $f_3 \geq 1.1f_2$;
3. Maximize $1/f_1 + 1/f_2$ subject to $f_2 \geq 1.1f_1$ [48].

Here, f_i is the frequency of the i -th flexible mode. Only the results for option 2 are shown, as it was the best-performing option of the three. Option 3 in particular resulted in a poorly defined geometry with large gray areas. The result of option 2 is shown in Fig. 7 (frq). It is important to note that these eigenfrequency optimizations have been performed under the requirement that all mechanical constraints are satisfied. Furthermore, in order to determine the performance of the eigenfrequency designs, the resulting structural design was used in closed loop, and the controller was optimized in the same way as for the integrated design. This means that the only difference between designs 7 (frq) and 7 (int) is that the former is optimized for maximum first eigenfrequency and subsequently maximum control performance, whereas the latter is optimized directly for closed-loop performance: all other constraints are identical and a similar mass penalty is included.

The topology optimization results for the integrated approach in which controller and structure are optimized simultaneously, is shown in Fig. 7 (int). The fact that gray areas are present in both designs presents a challenge for practical purposes. Several options exist to convert these designs to pure solid-void designs, for instance based on image-processing or thresholding techniques [49]. See [50] for examples in the present context.

With regards to computational time, both the integrated and eigenfrequency designs usually converge within about 30–40 iterations, requiring about 5 minutes for eigenfrequency optimization and about 15 minutes for the integrated approach, where the bulk of the time is spent computing mode sensitivities (cf. Sec. 4.1). This can possibly be improved in future work by exploiting parallel computing capabilities or fast re-analysis techniques. For both optimizations convergence is reached when the objective does not change more than a set tolerance between iterations in a relative sense.

The performance of both designs is compared in Figures 8 to 11. Note that all frequencies have been scaled with a constant factor for intellectual property reasons. The attenuation results in Fig. 8 are based upon the disturbance attenuation in the three control loops at 0.1 normalized frequency units on a decibel scale. First, it appears from Fig. 8 that the integrated approach (int) yields a far better improvement in disturbance attenuation compared to the eigenfrequency design (frq) in each of the motion control loops. Second, from Fig. 9 (int), it is clear that this performance is achieved while the first three natural frequencies are all *lower* than for the eigenfrequency design. So, in this case, it is not at all beneficial to raise the first three natural frequencies. Clearly, eigenfrequency design can only be performed

Figure 7: Example topologies comparing integrated and eigenfrequency designs. The performance figures are compared in Figures 8 to 11. Note that the initial design does not meet the mechanical requirements (Sec. 2.5).

Figure 8: Disturbance attenuation figures for the two designs (larger values imply better attenuation). The abbreviations frq and int refer to the designs shown in Fig. 7.

Figure 9: Natural frequencies (scaled) of the two designs. The abbreviations frq and int refer to the designs shown in Fig. 7. Mode shapes are shown in Figs. 13 and 14.

313 with a good understanding of which subset of modes is most relevant to overall performance, an understanding which
 314 is very hard to develop in general. In fact, the eigenfrequency design (frq) results in a lower average performance than
 315 the solid design while its lowest natural frequency is 30% higher than for the integrated design. Finally, the integrated
 316 approach also yields a slightly lower mass (Fig. 11), which is 5% below the eigenfrequency design.

317 The results obtained for this example demonstrate that non-trivial and fairly well-defined designs can be obtained,
 318 which could form a starting point for subsequent design. The integrated design (int) has on average about 20 dB better

Figure 10: Bandwidth values for the two designs. The abbreviations frq and int refer to the designs shown in Fig. 7.

319 disturbance attenuation at 0.1 normalized frequency units on each of the motion control axes.

Figure 11: Mass comparison (smaller is lighter). The abbreviations frq and int refer to the designs shown in Fig. 7.

320 5.2. Analysis of limitations

321 A careful analysis of the transfer functions shown in Fig. 12 can help to understand the performance differences
 322 between the eigenfrequency design and the integrated design. These figures show the effective loop gains (i.e., each
 323 rigid-body loop gain transfer function is generated with the other control loops closed). Two sensor locations are
 324 considered: a center location, Fig. 12a and the leftmost location, Fig. 12b (the results for the rightmost location are
 325 identical to the leftmost). It is important to realize that for any of the control loops, only one of these sensor locations
 326 will usually dictate the performance limitations encountered.

327 Analysing the three control loops (x , y and θ) for both designs reveals the following observations:

- 328 • Eigenfrequency design: For each of the rigid-body motion control loops, performance is limited by non-collocated
 329 flexible modes, which is observed from the 180° phase loss associated with these modes. For the x and θ con-
 330 trol loops this is the 3rd mode shown in Fig. 13c, which is what appears to be a second asymmetric beam-like
 331 bending mode of the stage. For the y control loop this is the 2nd mode shown in Fig. 13b, which is a symmetric
 332 second bending mode.
- 333 • Integrated design: The x control loop is limited by mode 6 shown in Fig. 14f, which is a complicated mode shape
 334 resembling a second asymmetric bending mode. The θ control loop is limited by mode 3 shown in Fig. 14c
 335 which also looks like a second asymmetric bending mode. For the y control loop it is clear that for the leftmost
 336 sensor position, a non-minimum phase zero is introduced when the other control loops are closed, which limits
 337 the bandwidth. This zero appears to be related to the first mode of the structure, shown in Fig. 14a.

338 Comparing the red and black lines, it is also clear that in all control loops the integrated design leads to higher loop
 339 gains (i.e., better disturbance rejection) subject to the same robustness and stability constraints.

340 The previous analysis, along with the mode shapes shown in Figs. 13 and 14, shows that there may be a clear
 341 advantage to the integrated design approach. It is very hard to predict a priori, for a complicated geometry, which
 342 modes are bandwidth-limiting. This results in a limited scope for eigenfrequency optimization procedures, unless
 343 one has very detailed knowledge on how each mode affects the controlled dynamics of the structure. Still, when the
 344 structural topology changes, this knowledge may become obsolete, since mode shapes and their spatial character may

345 change drastically. In contrast, the integrated approach directly takes into account the controlled dynamics, and is
 346 therefore able to modify all structural modes based on their relevance to achievable performance in a coordinated
 347 way.

348 While it is hard to draw general conclusions from this case study, a good illustration of the advantages of the
 349 integrated design approach is the following: the integrated approach results in the fact that only the 6th mode limits
 350 the x position control, whereas all other modes do not hinder the performance since they have been made barely
 351 observable or collocated (see the red lines in the x position dynamics in Figs. 12a and 12b).

352 Another observation is that the intricate topology of the integrated design leads to a denser eigenfrequency spec-
 353 trum at low frequencies. Figs. 13 and 14 show that the first 4 modes of design (frq) span the same frequency range as
 354 the first 6 modes of design (int).

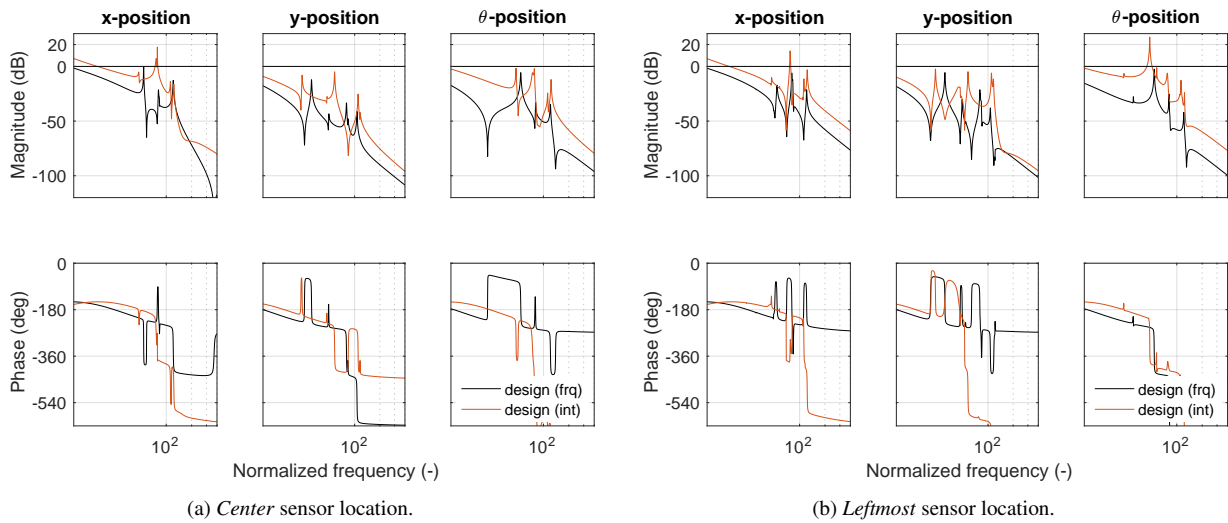

Figure 12: Effective loop gain transfer functions for two different sensor locations, comparing the eigenfrequency design (frq, black lines) with the integrated design (int, red lines).

355 A fundamental assumption underlying the gradient-based optimization approach is that it relies on small changes
 356 in the plant dynamics between iterations, meaning that the nature of consecutive poles and zeros in the transfer
 357 functions does not change. The process has difficulty when flexible modes start to cross each other. In those cases, the
 358 controlled system dynamics change drastically, implying that the controller parameters need to be changed abruptly.
 359 This may be less of an issue if the algorithm is applied to modify existing designs so that only small changes in the
 360 dynamics occur, but it needs attention to allow application to a wider set of problems. The issue could also potentially
 361 be overcome by performing separate controller optimization iterations after each structural design modification.

362 6. Discussion

363 Based on the example of optimizing a motion stage for closed-loop performance, the potential of the integrated
 364 gradient-based design methodology as a useful tool for the precision industry has been demonstrated. It can deal
 365 with sophisticated objective functions related to closed-loop performance, while including requirements and specifi-
 366 cations on mechanical behavior. The case study demonstrated that superior designs are generated using an integrated
 367 approach, compared to the conventional eigenfrequency maximization approach. The main focus of subsequent re-
 368 search will be to incorporate more constraints originating from actual practice and to move towards 3D design prob-
 369 lems. While in this article the focus was on mechanical and control system specifications, ultimately, incorporating
 370 thermal specifications will also be a necessity for precision applications.
