The superconducting proximity effect in semiconductor nanowires has recently enabled the study of new superconducting architectures, such as gate-tunable superconducting qubits and multiterminal Josephson junctions. As opposed to their metallic counterparts, the electron density in semiconductor nanosystems is tunable by external electrostatic gates providing a highly scalable and *in-situ* variation of the device properties. In addition, semiconductors with large g -factor and spin-orbit coupling have been shown to give rise to exotic phenomena in superconductivity, such as φ_0 Josephson junctions and the emergence of Majorana bound states. Here, we report microwave spectroscopy measurements that directly reveal the presence of Andreev bound states (ABS) in ballistic semiconductor channels. We show that the measured ABS spectra are the result of transport channels with gate-tunable, high transmission probabilities up to 0.9, which is required for gate-tunable Andreev qubits and beneficial for braiding schemes of Majorana states. For the first time, we detect excitations of a spin-split pair of ABS and observe symmetry-broken ABS, a direct consequence of the spin-orbit coupling in the semiconductor.

The linear conductance $G = \frac{2e^2}{h} \sum T_i$ of a nanostructure between two bulk leads [1] depends on the individual channel transmission probabilities, T_i . Embedding the same structure between two superconducting banks with a superconducting gap of Δ gives rise to Andreev bound states (ABS) [2]. If the junction length is much smaller than the superconducting coherence length, ξ , i.e. in the short junction limit, then the ABS levels depend on the phase difference ϕ between the leads according to [3]:

$$E_{\text{ABS},i}(\phi) = \pm \Delta \sqrt{1 - T_i \sin^2 \frac{\phi}{2}}. \quad (1)$$

These subgap states with $|E_{\text{ABS}}| \leq \Delta$ are localized in the vicinity of the nanostructure and extend into the banks over a length scale determined by ξ . Note that Eq. (1) is only valid in the absence of magnetic field, when each energy level is doubly degenerate.

Direct microwave spectroscopy has recently demonstrated the occupation of the ABS by exciting a Cooper pair in atomic junctions [4]. Unlike quasiparticle tunneling spectroscopy, which has also been used to detect ABS [5, 6], resonant excitation by microwaves is a charge parity-conserving process [7]. This property enables coherent control of ABS which is required for novel qubit architectures [8] and makes microwave spectroscopy a promising tool to detect Majorana bound states [9] in proximitized semiconductor systems [10–12].

We investigate ABS excitations in Josephson junctions that consist of indium arsenide (InAs) nanowires covered by epitaxial aluminium (Al) shells [13]. The junction, where the superconducting shell is removed, is 100 nm (device 1, see the red box in Fig. 1a) and 40 nm long (device 2), respectively. The nanowire is then embedded in a hybrid superconducting quantum interference device (SQUID) whose second arm is a conventional Al/AIO_x/Al tunnel junction (in yellow box), enabling the control of the phase drop ϕ by means of the applied magnetic flux Φ through the SQUID loop. In the limit of a negligible loop inductance and an asymmetric SQUID, where the Josephson coupling of the nanowire is much smaller than that of the tunnel junction, the applied phase φ mostly drops over the nanowire link: $\phi \approx \varphi = 2\pi\Phi/\Phi_0$, where $\Phi_0 = h/2e$ is the superconducting flux quantum. We measure the microwave response [4, 7] of the nanowire junction utilizing the circuit depicted in Fig. 1a, where a second Al/AIO_x/Al tunnel junction (in green box) is capacitively coupled to the hybrid SQUID and acts as a spectrometer. Further details on the fabrication process are given in the Supplementary Material.

In this circuit, inelastic Cooper-pair tunneling (ICPT, Fig. 1d) of the spectrometer junction is enabled by the dissipative environment and results in a DC current, I_{spec} [14]:

$$I_{\text{spec}} = \frac{I_{c,\text{spec}}^2 \text{Re}[Z(\omega)]}{2V_{\text{spec}}}. \quad (2)$$

Here $I_{c,\text{spec}}$ is the critical current of the spectrometer junction, V_{spec} is the applied voltage bias, and $Z(\omega)$ is the circuit impedance at a frequency $\omega = 2eV_{\text{spec}}/\hbar$. Since $Z(\omega)$ peaks at the resonant frequencies of the hybrid

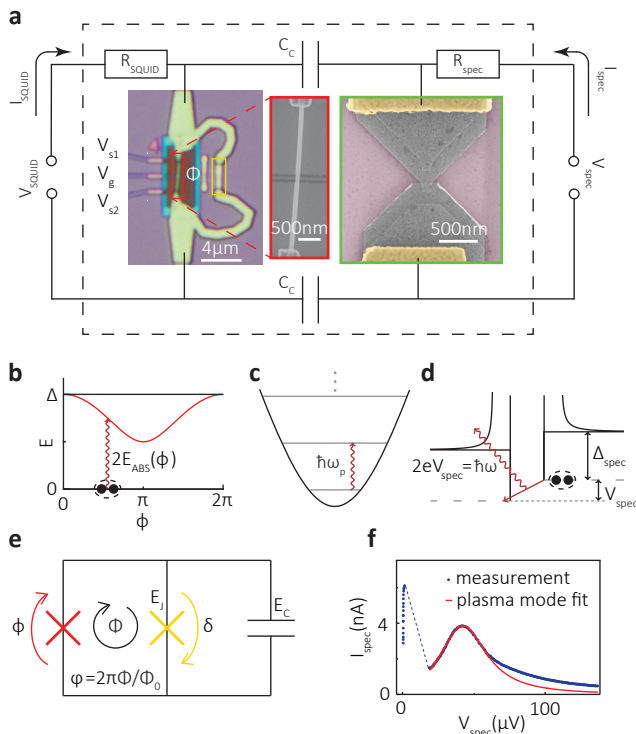

FIG. 1. Device schematics and working principle. (a) Equivalent circuit diagram: Bright field optical image of the hybrid SQUID with one InAs semiconductor nanowire weak link (scanning electron micrograph, in the red box) and an Al/AIO_x/Al tunnel junction (enclosed by the yellow box). The SQUID is capacitively coupled to the spectrometer Al/AIO_x/Al Josephson junction (scanning electron micrograph, in the green box) via C_c . The transmission of the semiconductor channel is tuned by the gate voltage, V_g . Additional gates near the electrodes are kept at a constant voltage $V_{s1,2}$. Circuit elements within the dashed box are located on-chip, thermally anchored to 12 mK. (b) and (c) excitations of the hybrid SQUID: the Andreev bound state at $\hbar\omega = 2E_{\text{ABS}}$ (b) and the plasma oscillations at $\hbar\omega = \hbar\omega_p$ (c) are excited by a photon energy $\hbar\omega = 2eV_{\text{spec}}$ set by the DC voltage bias of the spectrometer (d) with a superconducting gap Δ_{spec} . (e) Schematic circuit diagram of the hybrid SQUID. The total phase $\varphi = \phi + \delta$ is determined by the applied flux Φ . (f) The measured $I(V)$ trace of the spectrometer junction with the nanowire in full depletion, i.e. in the absence of ABS excitations. The red solid line shows the fit to the circuit model of a single resonance centered at $\hbar\omega_p$, see text. Images and data were all taken on device 1.

SQUID [4, 14], so does the DC current I_{spec} , allowing us to measure the ABS excitation energies of the nanowire junction (Fig. 1b), as well as the plasma frequency of the SQUID (Fig. 1c).

First we characterize the contribution of the plasma mode with the nanowire junction gated to full depletion, i.e. $G = 0$. We show the $I(V)$ curve of the spectrometer junction of device 1 in Fig. 1f, where we find a single peak centered at $\hbar\omega_p/2 = eV_{\text{spec}} = 46 \mu\text{eV}$ and a quality factor $Q \approx 1$. In the limit of $E_C \ll E_J$, $\hbar\omega_p = \sqrt{2E_C E_J}$,

where E_C is the charging energy of the circuit and E_J is the Josephson coupling of the tunnel junction (Fig. 1e). Estimating $E_J = 165 \mu\text{eV}$ from the normal state resistance [15], this measurement allows us to determine $E_C = 25.4 \mu\text{eV}$ (see the Supplementary Material). The choice of a low quality factor in combination with a characteristic impedance $Z_0 = 551 \Omega \ll R_q = h/4e^2$ ensures the suppression of higher order transitions and parasitic resonances.

Next, we investigate the spectrometer response as a function of the gate voltage V_g applied to the nanowire. Note that the spectrometer response to the ABS transitions is superimposed on the plasma resonance. In order to achieve a better visibility of the ABS lines, we display $-d^2 I_{\text{spec}}/dV_{\text{spec}}^2(V_{\text{spec}})$ rather than $I_{\text{spec}}(V_{\text{spec}})$ (see Supplementary Material for comparison). In the presence of ABS, the spectrum exhibits peaks at frequencies where $\hbar\omega = 2E_{\text{ABS},i}$ [7]. In Fig. 2a, we monitor the appearance of these peaks for an applied phase $\varphi = \pi$, where the ABS energy of Eq. (1) is $E_{\text{ABS},i}(\pi) = \Delta\sqrt{1 - T_i}$. Notably, for V_g values close to full depletion (see red bar in Fig. 2a), we see a gradual decrease of $E_{\text{ABS}}(\pi)$ with increasing V_g (black circles in Fig. 2e). In this regime, we find a good correspondence with Eq. (1), assuming single channel transport, $G = \frac{2e^2}{h}T$ (red solid line in Fig. 2e, see the Supplementary material on the details of the measurement of G). However, the observed $\Delta = 122 \mu\text{eV}$ is smaller than the $\Delta_{\text{Al}} \approx 200 \mu\text{eV}$ of the thin film Al contacts, in agreement with the presence of induced superconductivity in the nanowire [16]. Increasing V_g further, we observe a sequential appearance of peaks, which we attribute to the opening of multiple transport channels in the weak link and the consequent formation of multiple ABS [3] as the Fermi level, E_F increases. We also find a strong variation of E_{ABS} with V_g similarly to earlier experiments [17–19]. We attribute this observation to mesoscopic fluctuations in the presence of weak disorder [3], such that the mean free path of the charge carriers is comparable to the channel length.

Now we turn to the flux dependence of the observed spectrum, shown in Fig. 2b and 2c for two distinct gate configurations. We find a qualitative agreement with Eq. (1) with one transport channel in Fig. 2b and several channels in Fig. 2c confirming that our device is in the short junction limit. In addition, we observe the plasma mode at $eV_{\text{spec}} < 50 \mu\text{eV}$. We also find that the plasma mode $\hbar\omega_p$ oscillates with φ when the nanowire is gated to host open transport channels. This is expected due to the Josephson coupling of the nanowire becoming comparable to E_J , which also causes a finite phase drop, δ , over the tunnel junction (see Supplementary Material). We also note the presence of additional, weakly visible lines in the spectrum which could be attributed to higher order processes [4]. However, we did not identify the nature of these excitations, and we focus on the main transitions throughout the current work.

FIG. 2. **Gate dependence of Andreev bound states.** (a) $-d^2I/dV^2$ of the spectrometer junction as a function of V_g at $\varphi = \pi$, where $E_{\text{ABS},i} = \Delta\sqrt{1-T_i}$ in the short junction limit. Panels (b) and (c): $-d^2I/dV^2$ of the spectrometer junction as a function of $\varphi = 2\pi\Phi/\Phi_0$ for one channel (b) and several channels (c). The qualitative agreement of the line shapes with Eq. (1) confirms the short junction behaviour. Arrows in panel (a) indicate V_g for these measurements. Weakly visible vertically shifted replicas of the ABS lines indicate higher order transitions, see text. (d) Strong hybridization between the ABS excitation and the plasma mode with a level repulsion of $\varepsilon = 22 \mu\text{eV}$ at the yellow dashed line. (e) $E_{\text{ABS}}(\varphi = \pi)$ as a function of the DC linear conductance G of the nanowire weak link in the gate span denoted by the red bar in panel (a). The error bars correspond to the linewidth of the measured signal. The solid red line shows the prediction of the single channel model with $\Delta = 122 \mu\text{eV} \pm 3 \mu\text{eV}$, see text. All data was taken on device 1. Grey regions denote lack of data due to bias instability of the circuit.

In addition, we observe the occurrence of avoided crossings between the Andreev and plasma modes, as shown in Fig. 2d at $\varphi = \pi$. These avoided crossings require $\hbar\omega_p \approx 2\Delta\sqrt{1-T}$, which translates to a high transmission probability $T \approx 0.8 - 0.9$, and demonstrates the hybridization between the ABS excitation and the plasma mode. The coupling between these two degrees of freedom has previously been derived [7, 20] (see Supplementary Material), leading to a perturbative estimate for the energy splitting $\varepsilon \approx \Delta T (E_C/2E_J)^{1/4} \approx 40 - 70 \mu\text{eV}$, similar to the observed value of $22 \mu\text{eV}$. The discrepancy is fully resolved in the numerical analysis of the circuit model developed below.

We provide a unified description of the energy spectrum of the circuit as a whole, and consider the following Hamiltonian for the hybrid SQUID (Fig. 1e) [20]:

$$\hat{H} = E_C \hat{N}^2 + E_J (1 - \cos \hat{\delta}) + \hat{H}_{\text{ABS}}(\varphi - \hat{\delta}). \quad (3)$$

Here $\hat{\delta}$ is the operator of the phase difference across the tunnel junction, conjugate to the charge operator \hat{N} , $[\hat{\delta}, \hat{N}] = i$. The first two terms in Eq. (3) represent the charging energy of the circuit and the Josephson energy of the tunnel junction (Fig. 1e). The last term describes the quantum dynamics of a single-channel short weak link [21, 22], which depends on Δ and T . For the analytic form of \hat{H}_{ABS} , see the Supplementary Material. To fully account for the coupling between the ABS excitation and the quantum dynamics of the phase across the SQUID, we numerically solve the eigenvalue problem $\hat{H}\Psi = E\Psi$ and determine the transition frequencies $\hbar\omega = E - E_{\text{GS}}$

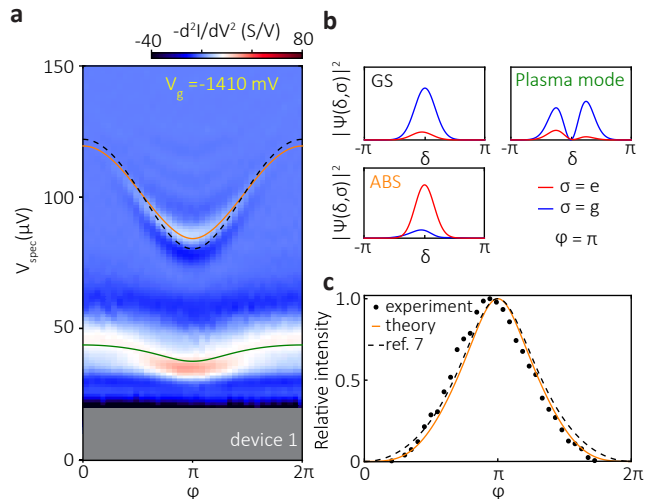

FIG. 3. **Theoretical description of the transitions.** (a) Solid lines denote the transitions identified by the model described in the text, with Δ and T being free parameters. The experimental dataset is the same as the one shown in Fig. 2b. The dashed line shows Eq. (1) for the fitted $\Delta = 122 \mu\text{eV}$ and $T = 0.57$. (b) The probability density $|\Psi(\delta, \sigma)|^2$ in the ground state of the hybrid SQUID (GS), and in the two excited states depicted in panel (a), respectively. The weight in the ABS ground state ($\sigma = g$) and in the ABS excited state ($\sigma = e$) distinguishes between the plasma mode and the ABS. (c) The measured relative intensity of the ABS transition (black circles) compared to the theoretical expectation based on Eq. (3) (orange solid line) and from [7] (black dashed line) with no additional fitting parameters.

with E_{GS} being the ground state energy.

This procedure allows us to fit the experimental data, and we find a good quantitative agreement as shown in Fig. 3a for a dataset taken at $V_g = -1410$ mV with the fit parameters $\Delta = 122 \mu\text{eV}$ and $T = 0.57$. The previously identified circuit parameters E_J and E_C are kept fixed during the fit. We note that the observed ABS transition (orange solid line) only slightly deviates from Eq. (1) (black dashed line). The modulation of the plasma frequency (green solid line) is then defined by the model Hamiltonian with no additional fit parameters. We further confirm the nature of the plasma and ABS excitations by evaluating the probability density $|\Psi(\delta, \sigma)|^2$ of the eigenfunctions of Eq. (3) at $\varphi = \pi$ (Fig. 3b). In the ground state of \hat{H} (GS) and in the state corresponding to the plasma excitation (green line in Fig. 3a), the probability density is much higher in the ground state of the weak link ($\sigma = g$, blue line) than in the excited state ($\sigma = e$, red line). In contrast, the next observed transition (orange line in Fig. 3a) gives rise to a higher contribution from $\sigma = e$ confirming our interpretation of the experimental data in terms of ABS excitations. Furthermore, the model can also describe measurement data with T close to 1, where it accurately accounts for the avoided crossings between the ABS and plasma spectral lines (see the Supplementary Material for a dataset with $T = 0.9$).

In Fig. 3c we show the visibility of the ABS transition as a function of the applied phase φ , which is proportional to the absorption rate of the weak link, predicted to be $\propto T^2(1-T)\sin^4(\varphi/2) \times \Delta^2/E_{ABS}^2(\varphi)$ [7]. We note that in the experimental data the maximum of the intensity is slightly shifted from its expected position at $\varphi = \pi$. This minor deviation may stem from the uncertainty of the flux calibration. Nevertheless, using $T = 0.57$, obtained from the fit in Fig. 3a, we find a good agreement with no adjustable parameters (black dashed line). A similarly good correspondence is also found with the full numerical model (orange line) based on Eq. (3).

We now discuss the evolution of the ABS as a function of an in-plane magnetic field B aligned parallel to the nanowire axis, which is perpendicular to the internal Rashba spin-orbit field (see the inset in Fig. 4b for measurement geometry). The applied field lifts the Kramers degeneracy of the energy spectrum, splitting each Andreev doublet into a pair $E_{ABS}^{\pm}(\phi)$. For small B , the splitting $E_{ABS}^+(\phi) - E_{ABS}^-(\phi)$ is linear in B , due to the Zeeman effect. However, the spin-split single particle levels are not accessible by microwave spectroscopy, which can only induce transitions to a final state with two excited quasiparticles. Thus we can only measure $E_{tot}(\phi) = E_{ABS}^+(\phi) + E_{ABS}^-(\phi)$ and expect no split of the measured spectral lines. The experimental data (Fig. 4a) shows that E_{tot} decreases with B , while the lineshape remains qualitatively intact.

In order to explain the field dependence of E_{tot} , we

FIG. 4. Spectroscopy of spin-split Andreev bound states in a Rashba nanowire. Panel (a) shows the flux dependence of the Andreev bound states at $B = 0, 100$ and 300 mT, respectively, applied parallel to the nanowire. The zero-field fit yields to $T = 0.56$ and $\Delta = 152 \mu\text{eV}$. Dash lines depict the fit of $E_{tot}(\phi) = E_{ABS}^+(\phi) + E_{ABS}^-(\phi)$ to the model described in the text. (b) Black circles show the measured $E_{tot}(\pi)$ as a function of B . The error bars correspond to the linewidth of the measured signal. The dashed line depicts the fit to the theory with $g = 14.7 \pm 0.6$ and $\sqrt{E_{SO}E_F}/\Delta = 0.32 \pm 0.02$, see text. The Zeeman-split ABS levels $E_{ABS}^{\pm}(\pi)$ and the proximity-induced gap $\Delta(B)$ obtained from the model are shown as visual guides. The dotted line depicts the expected behavior of $E_{tot}(B)$ in the presence of a strong orbital magnetic field with $B_* = 400$ mT and weak spin-orbit coupling, see text. (c) $E_{ABS}^{\pm}(\phi)$ computed at $B = 100$ mT are shown as blue and red solid lines, together with the calculated transition energy $E_{tot}(\phi)$ (black dashed line). The experimental data was taken on device 2 at $V_g = 140$ mV. Grey regions denote lack of data due to bias instability of the circuit.

study the behaviour of ABS in a simple model consisting of a short Josephson junction in a one-dimensional quantum wire with proximity-induced superconductivity, Rashba spin-orbit and an applied Zeeman field parallel to the wire [10, 11, 23]. Within this model, we are able to find E_{ABS}^+ and E_{ABS}^- , and reproduce the observed quadratic decrease of the measured $E_{tot}(\pi)$ (black circles in Fig. 4b). Initially, as B is increased, the proximity-induced gap $\Delta(B)$ is suppressed (black solid line), while the energy $E_{ABS}^+(\pi)$ (blue solid line) increases due to the Zeeman split of the ABS. However, a crossing of the discrete ABS level with the continuum is avoided due to the presence of spin-orbit coupling, which prevents level crossings in the energy spectrum by breaking spin-rotation symmetry. The repulsion between the ABS level and the continuum causes a downward bending of

$E_{\text{ABS}}^+(\pi)$, in turn causing a decrease in $E_{\text{tot}}(\pi)$ (black dashed line).

We perform the calculations in the limit where the Fermi level E_F in the wire is well above the Zeeman energy $E_Z = \frac{1}{2}g\mu_B B$ and the spin-orbit energy $E_{\text{SO}} = m\alpha^2/2\hbar^2$ with m the effective mass and α the Rashba spin-orbit coupling constant. In this case and in the short junction limit, the ratio $E_{\text{tot}}(\pi)/\Delta$ is a function of just two dimensionless parameters: E_Z/Δ and $\sqrt{E_{\text{SO}}E_F}/\Delta$. First we extract $\Delta = 152 \mu\text{eV}$ and $T = 0.56$ at $B = 0$ (leftmost panel in Fig. 4a). Then we perform a global fit on $E_{\text{tot}}(\phi)$ at all B values and obtain a quantitative agreement with the theory for $g = 14.7 \pm 0.6$, which is in line with expected g -factor values in InAs nanowires [24–26] and $\sqrt{E_{\text{SO}}E_F}/\Delta = 0.32 \pm 0.02$. This model is consistent assuming $E_F > E_Z \approx 100 \mu\text{eV}$ at 300 mT. Thus we attain an upper bound $E_{\text{SO}} \lesssim 24 \mu\text{eV}$, equivalent to a Rashba parameter $\alpha \lesssim 0.12 \text{ eV\AA}$ in correspondence with earlier measurements on the same nanowires [26]. However, assuming the opposite limit, $E_F \approx 0$, the theory is not in agreement with the experimental data (see the Supplementary Material).

The theoretical energy spectrum shown in Fig. 4b predicts a ground state fermion-parity switch of the junction at a field $B_{\text{sw}} \approx 400 \text{ mT}$, at which the lowest ABS level $E_{\text{tot}}^-(\pi) = 0$ (red line in Fig. 4b). This parity switch inhibits the resonant excitation of the Zeeman-split ABS levels [27] thus preventing microwave spectroscopy measurements for $B > B_{\text{sw}}$. This prediction is in agreement with the vanishing visibility of the ABS line at $B \approx B_{\text{sw}}$ in the experiment.

In addition to the interplay of spin-orbit and Zeeman couplings, the orbital effect of the magnetic field [28] is a second possible cause for the decrease of the ABS transition energy. Orbital depairing influences the proximity-induced pairing and results in a quadratic decrease of the induced superconducting gap: $\Delta(B) = \Delta(1 - B^2/B_*^2)$, where $B_* \sim \Phi_0/A$ and A is the cross-section of the nanowire. A simple model which includes both orbital and Zeeman effect, but no spin-orbit coupling, yields $B_* \approx 400 \text{ mT}$ when fitted to the experimental data (see Supplementary Material for details). In this case, the fit is insensitive to the value of the g -factor. However, the model also predicts the occurrence, at $\phi = \pi$, of a fermion-parity switch at a field $B_{\text{sw}} < B_*$ whose value depends on the g -factor. Because agreement with the experimental data imposes the condition that $B_{\text{sw}} > 300 \text{ mT}$, in the Supplementary Material we show that this scenario requires $g \lesssim 5$, which is lower than g -factor values measured earlier in InAs nanowire channels [24–26].

Furthermore, we can consider the qualitative effect of the inclusion of a weak spin-orbit coupling ($E_{\text{SO}} \ll \Delta$) in this model containing only the orbital and Zeeman effects. We note that, without spin-orbit coupling, the upper Andreev level $E_{\text{ABS}}^+(B)$ crosses a continuum of states $\Delta(B)$ with opposite spin upon increasing the mag-

FIG. 5. Time-reversal symmetry-broken ABS in magnetic field. The symmetry axis at $\phi = \pi$ at zero magnetic field is denoted by yellow dashed line. Note that at $B = 40 \text{ mT}$ the observed spectrum does not obey the mirror symmetry with respect to the same line. The data was taken on device 1 at $V_g = -20 \text{ mV}$. Grey regions denote lack of data due to bias instability of the circuit.

netic field (see Fig. S11c in the Supplementary Material). The crossing happens at a field of B_{cross} whose value depends on the g -factor: using the upper bound for g derived in the last paragraph, $g \approx 5$, we can estimate $B_{\text{cross}} \approx 150 \text{ mT}$. At this magnetic field, a weak spin-orbit coupling results in an avoided crossing between the Andreev level $E_{\text{ABS}}^+(B)$ and the continuum. As a consequence, when $B > B_{\text{cross}}$, the energy $E_{\text{ABS}}^+(B)$ is bounded by the edge of the continuum and it is markedly lower than its value in the absence of spin-orbit coupling. In turn, this results in a decrease of the transition energy $E_{\text{tot}}(B)$ at $B > B_{\text{cross}}$, to the extent that such a model containing the joint effect of orbital depairing and weak spin-orbit coupling would depart from the experimental data in the range $150 \text{ mT} < B < 300 \text{ mT}$ (see dotted line in Fig. 4b). Thus, although based on the geometry of the experiment we cannot rule out the presence of an orbital effect of the magnetic field, these considerations imply that it does not play a dominant role in the quadratic suppression of the transition energy in the present measurements.

We finally note that in all cases we neglect the effect of B on the Al thin film, justified by its in-plane critical magnetic field exceeding 2 T [29].

We present the ABS spectrum in the presence of several transport channels in Fig. 5. While at zero magnetic field (left panel) the data is symmetric around $\phi = \pi$, in a finite magnetic field (right panel) the data exhibits an asymmetric flux dependence (see the yellow dashed line as a guide to the eye). This should be contrasted with Fig. 4a where the data for a single-channel wire are presented at different values of the magnetic field: each

of the traces is symmetric around $\varphi = \pi$. This behavior agrees with theoretical calculations in the short-junction limit, which show that this asymmetry can arise in a Josephson junction with broken time-reversal and spin-rotation symmetries as well as more than one transport channel [30]. While the data is asymmetric with respect to $\varphi = \pi$, there is no visible shift of the local energy minima away from this point. This observation is consistent with the absence of an anomalous Josephson current [31–33] for our specific field configuration (magnetic field parallel to the wire), in agreement with theoretical expectations [34–36].

In conclusion, we have presented microwave spectroscopy of Andreev bound states in semiconductor channels where the conductive modes are tuned by electrostatic gates and we have demonstrated the effect of Zeeman splitting and spin-orbit coupling. The microwave spectroscopy measurements shown here could provide a new tool for quantitative studies of Majorana bound states, complementing quasiparticle tunneling experiments [12, 24]. Furthermore, we have provided direct evidence for the time-reversal symmetry breaking of the Andreev bound state spectrum in a multichannel ballistic system. This result paves the way to novel Josephson circuits, where the critical current depends on the current direction, leading to supercurrent rectification effects [37, 38] tuned by electrostatic gates.

Microwave spectroscopy of spinful Andreev bound states in ballistic semiconductor Josephson junctions

DEVICE FABRICATION

The devices are fabricated on commercially available undoped Si wafers with a 285 nm thick thermally grown SiO_x layer using positive tone electron beam lithography. First, the electrostatic gates and the lower plane of the coupling capacitors are defined and Ti/Au (5 nm/15 nm) is deposited in a high-vacuum electron-beam evaporation chamber. Next, the decoupling resistors are created using Cr/Pt (5 nm/25 nm) with a track width of 100 nm, resulting in a characteristic resistance of $100 \Omega/\mu\text{m}$. Then, a 30 nm thick SiN_x layer is sputtered and patterned to form the insulation for the coupling capacitors and the gates. We infer $C_c = 400$ fF based on the surface area of $6.5 \times 30 \mu\text{m}^2$ and a typical dielectric constant $\epsilon_r = 7$.

In the following step, the tunnel junctions are created using the Dolan bridge technique by depositing 9 and 11 nm thick layers of Al with an intermediate oxidization step *in-situ* at 1.4 mbar for 8 minutes. Then, the top plane of the coupling capacitors is defined and evaporated (Ti/Au, 20 nm/100 nm) after an *in-situ* Ar milling step to enable metallic contact to the Al layers. Next, the InAs nanowire is deterministically deposited with a micro-manipulator on the gate pattern [40].

The channel of device 1 is defined by wet chemical etch of the aluminium shell using Transene D at 54°C for 12 seconds. The channel of device 2 is determined by *in-situ* patterning, where an adjacent nanowire casted a shadow during the epitaxial deposition of aluminium [41]. The superconducting layer thickness was approximately 10 nm for both devices deposited on two facets.

Finally, the nanowire is contacted to the rest of the circuit by performing Ar plasma milling and subsequent NbTiN sputter deposition to form the loop of the hybrid SQUID. We show the design parameters of the devices in Table S1.

	Device 1	Device 2
Channel length (nm)	100	40
Tunnel junction area (nm^2)	400×120	200×120
Flux periodicity (μT)	38	120
Spectrometer junction area (nm^2)	120×120	120×120

MEASUREMENT SETUP

FIG. S1. **Detailed schematics of the measurement setup.** The inset of panel (a) shows a bright field optical image of device 1. The solid black box denotes the radiation shielded environment thermally anchored to 12 mK. (b) On-chip lumped circuit elements attached to the hybrid SQUID (on the left) and the spectrometer Josephson junction (on the right).

The measurements were performed in a Leiden Cryogenics CF-1200 dry dilution refrigerator with a base temperature of 12 mK equipped with Cu/Ni shielded twisted pair cables thermally anchored at all stages of the refrigerator to facilitate thermalization. Noise filtering is performed by a set of π -LC filters (~ 100 MHz) at room temperature and copper-powder filters (~ 1 GHz) in combination with two-pole RC filters (~ 100 kHz) at base temperature for each measurement line. The schematics of the setup is shown in Fig. S1.

DEVICE CIRCUIT PARAMETERS

We characterise the circuit based on the plasma resonance observed with the semiconductor nanowire gated to zero conductance, i.e. full depletion. In this regime, we infer the environmental impedance $\text{Re}[Z(\omega)]$ based on Eq. (2) in the main text and assume the following form, which is valid for a parallel LCR circuit:

$$\text{Re}[Z(x)] = \frac{Z_0 Q}{1 + \frac{Q^2}{x^2}(1 - x^2)^2}, \quad (\text{S1})$$

with $x = \omega/\omega_0$ the dimensionless frequency. The resonance of the circuit is centered at $\omega_0 = (LC)^{-1/2}$ with a quality factor of $Q = R\sqrt{\frac{C}{L}}$ and a characteristic impedance of $Z_0 = \sqrt{L/C}$. Consistently with this single mode circuit, we find one peak in the $I(V)$ trace of the spectrometer that we fit to Eq. (S1) (Fig. S2). We find a good quantitative agreement near the resonance peak, however the theoretical curve consistently deviates at higher voltages, i.e. higher frequencies. We attribute this discrepancy to additional losses or other resonant modes of the circuit not accounted for by Eq. (S1).

In addition, we use the superconducting gap and the linear resistance of the junctions to determine the Josephson energy E_J and the Josephson inductance L_J . With these, we infer the circuit parameters listed in Table S2.

FIG. S2. **Plasma resonance of the circuit.** The measured (black dots) and fitted (solid red line) $I(V)$ trace of the spectrometer junction for device 1 (a) and for device 2 (b) respectively, with the nanowire in full depletion. The fits are based on Eq. (S1), see text. Note that we omitted the supercurrent branch for clarity. In panel (b), the inset shows the spectrometer response to an in-plane magnetic field of 300 mT.

FIG. S3. **Large scale $I(V)$ trace of the spectrometer junction.** The subgap features are shown in detail in Fig. S2a. The back-bending near $eV_{\text{spec}} \approx 2\Delta_{\text{spec}} = 482 \mu\text{eV}$ is attributed to a local overheating of the junction due to a large quasiparticle current density above the gap edge. The data was taken on device 1.

	Device 1	Device 2
Tunnel junction resistance R_J (k Ω)	4.80	10.7
Tunnel junction gap Δ_J (μeV)	245	250
Tunnel junction critical current $I_{c,J} = \frac{\pi\Delta_J}{2eR_J}$ (nA)	80.2	36.7
$E_J = \frac{\hbar I_{c,J}}{2e}$ (μeV)	165	75.5
Tunnel junction inductance $L_J = \frac{\Phi_0}{2\pi I_{c,J}}$ (nH)	4.10	8.94
Spectrometer resistance R_{spec} (k Ω)	17.1	18.4
Spectrometer gap Δ_{spec} (μeV)	241	249
Spectrometer critical current $I_{c,\text{spec}} = \frac{\pi\Delta_{\text{spec}}}{2eR_{\text{spec}}}$ (nA)	22.2	21.3
Shunt resistance R (Ω)	634	743
Shunt capacitance C (fF)	12.6	11.1
Charging energy $E_c = \frac{2e^2}{C}$ (μeV)	25.44	29.1
Plasma frequency $f_p = \frac{1}{2\pi\sqrt{L_J C}}$ (GHz)	22.9	16.0
Characteristic impedance $Z_0 = \sqrt{\frac{L_J}{C}}$ (Ω)	551	897
Quality factor $Q = R\sqrt{\frac{C}{L_J}}$	1.15	0.83

TABLE S2. **Circuit parameters of the devices featured in the current study.**

ADDITIONAL DATASETS

Spectrum analysis

Peaks in the $I(V)$ trace of the spectrometer correspond to peaks in $\text{Re}[Z(\omega)]$, i.e. allowed transitions of the environment coupled to the spectrometer. In order to remove the smooth background of the plasma mode (see Fig. S2), we evaluate $-d^2I/dV^2(V)$, the second derivative of the $I(V)$ to find peaks in $\text{Re}[Z(\omega)]$ after applying a Gaussian low pass filter with standard deviation of $1.5\ \mu\text{V}$. We benchmark this method in Fig. S4, and find that the peaks where $-d^2I/dV^2(V) > 0$ correspond to the peaks in $I(V)$ and hence $-d^2I/dV^2(V)$ is a good measure of the transitions detected by the spectrometer junction.

FIG. S4. **Spectrum analysis by second derivative.** The $I(V)$ (red line, left axis) and the corresponding $-d^2I/dV^2(V)$ trace (black line, right axis) of the spectrometer showing the same peaks denoted by dashed lines. Note that only peaks above $-d^2I/dV^2(V) = 0$ (grey horizontal line) correspond to actual transitions. This dataset was taken on device 1, at $V_g = -1410\ \text{mV}$, phase biased to $\varphi = \pi$.

Alternatively, the background can be removed by linewise subtracting the detector response at $\varphi = 0$ [42], where the ABS does not contribute to the spectrometer response [43]. We show the result of this analysis in Fig. S5. Notably, the phase dependence of the plasma mode gives rise to additional features near $\varphi = \pi$. Furthermore, datasets exhibiting hybridization between the ABS and plasma mode cannot be evaluated by this method. However, the line subtraction and the second derivative are in agreement if there is sufficient spacing between the plasma mode and the ABS line (see Fig. 2b and Fig. S5 for comparison).

FIG. S5. **Spectrum analysis by background subtraction.** (a) $I_{\text{sub}}(\varphi) = I_{\text{spec}}(\varphi) - I_{\text{spec}}(\varphi = 0)$ spectrometer current after subtracting the line trace at $\varphi = 0$. (b) Single linetrace of the raw data $I_{\text{spec}}(\varphi = \pi)$ (red line, left axis) and $I_{\text{sub}}(\varphi = \pi)$ (black line, right axis). This dataset was taken on device 1, at $V_g = -1410 \text{ mV}$.

I(V) trace of the hybrid SQUID

We measure the $I(V)$ trace of the hybrid SQUID as a function of the gate voltage V_g at $V_{\text{spec}} = 0$ (Fig. S6) and find that the subgap conductance increases with increasing gate voltage, in qualitative agreement with the contribution of multiple Andreev reflection (MAR). The zero voltage data corresponds to the supercurrent branch and the dashed lines denote the bias range where there is no data due to the bias instability of the driving circuit. In addition, we find a back-bending at the gap edge $eV_{\text{SQUID}} = 2\Delta_J$, attributed to self-heating effects in the tunnel junction.

We evaluate G in Fig. 2e of the main text in the bias voltage range $-V_{\text{SQUID}} = 350 \dots 430 \mu\text{V} > 2\Delta$. We note that due to the soft superconducting gap in the nanowire junction, we did not identify MAR features after subtracting the current background of the tunnel junction.

FIG. S6. **The $I(V)$ trace of the hybrid SQUID.** At $V_g = -1.75 \text{ V}$, the nanowire is in full depletion, thus the corresponding $I(V)$ trace represents the Al/AlO_x/Al tunnel junction in the hybrid SQUID. The bias voltage V_{SQUID} was swept from the left to the right. The data was taken on device 1.

Fit of ABS with high transmission

FIG. S7. **Experimental data and fit to the theory for ABS with high transmission.** In this figure we show the numerical fit to the model of Eq. (3), similarly to Fig. 3a, but for a different dataset taken at $V_g = -1.525$ V on device 1. The figure shows that the model of Eq. (3) can accurately predict the avoided crossing originating in the coupling between the ABS and the plasma mode. Best-fit parameters are $\Delta = 97.5 \pm 1.7 \mu\text{eV}$ and $T = 0.90 \pm 0.01$. Dashed line denotes the undressed Andreev level defined by Eq. (1) in the main text. We note that the extracted value for Δ is lower than in Fig. 3a. This may stem from the fit underestimating the gap, since most of the datapoints are around $\varphi = \pi$, or due to a genuine dependence of Δ on V_g because of the change in the wavefunction overlap as a result of the electrostatic gating [44]. In panel (b), we show the probability density for the ground state (GS) and the two observed excited states denoted by the green and orange lines, respectively in panel (a) at $\varphi = \pi$.

Time-reversal symmetry-broken ABS in bipolar magnetic field

FIG. S8. **Symmetry-broken ABS in a bipolar magnetic field.** The full spectrum is symmetric around $\varphi = \pi$ at zero magnetic field (center panel) with the mirror axis denoted by the yellow dashed line. Note the asymmetry of the two lowermost ABS transitions at $B = \pm 40\text{ mT}$. The antisymmetric contribution is most visible at $V_{\text{spec}} \approx 100\ \mu\text{V}$, which develops an opposite shift for positive and negative magnetic fields, respectively. The data was taken on device 1 at $V_g = -770\text{ mV}$. Grey regions denote lack of data due to bias instability of the circuit.

THEORY

Estimate of the ABS-plasma resonance avoided crossing

Before describing the quantum model of the circuit in detail, we discuss the estimate for the energy splitting at the avoided crossing between the ABS transition and the plasma frequency shown in Fig. 2d.

For simplicity, we model the plasma oscillations as a bosonic mode with a flux-independent frequency given by $\hbar\omega_p = \sqrt{2E_J E_C}$, and the weak link as a two-level system, with energies $\pm E_{\text{ABS}}(\varphi)$ defined by Eq. (1) in the main text. This system with the two independent degrees of freedom is described by the Hamiltonian $\hat{H}_0 = \hbar\omega_p(\hat{a}^\dagger\hat{a} + \frac{1}{2}) + E_{\text{ABS}}\hat{\sigma}_3$. Next, we add the coupling term corresponding to the excitation of the weak link due to the voltage oscillations induced by the junction in the form

$$H_g(\varphi) = g(\varphi)\sqrt{z}(\hat{a}^\dagger + \hat{a})\hat{\sigma}_1. \quad (\text{S2})$$

where $z = \sqrt{E_C/2E_J}$. This term describes a linear coupling between the two-level system and the phase difference across the junction. $g(\varphi)$ is then given by the current matrix element between the ground and excited states of the weak link, which was derived in Ref. [43]:

$$g(\varphi) = \Delta T \sqrt{1-T} \sin^2(\varphi/2) \frac{\Delta}{E_{\text{ABS}}(\varphi)}. \quad (\text{S3})$$

The square of this current matrix element gives the microwave absorption rate of the weak link, plotted in Fig. 3c (black dashed line) of the main text. From the coupling Hamiltonian, we immediately obtain that at $\varphi = \pi$, the splitting is

$$\varepsilon = \Delta T \sqrt{z} \quad (\text{S4})$$

which is the expression used for the estimate in the main text. We note that Eq. (S4) is the lowest-order estimate of the avoided crossing in the small parameter \sqrt{z} . The relatively high value $\sqrt{z} \approx 0.52$ of device 1 may explain the discrepancy between this simple estimate and the observed value, which is captured by the full model, see Fig. S7. Finally, we note that the expression (S3) was also derived in Ref. [45] starting from the full model (see next section). In particular, the quantity $\Omega_x(\varphi)$ in Ref. [45] is equal to $\sqrt{z}g(\varphi)$.

Hamiltonian description of the hybrid SQUID

We now describe the theoretical model of the hybrid SQUID that was used to fit the experimental data. Our model is based on Refs. [46] and [47]. The Hamiltonian of the model is Eq. (3) of the main text, repeated here for convenience:

$$\hat{H} = E_C \hat{N}^2 + E_J(1 - \cos \hat{\delta}) + \hat{H}_{\text{ABS}}(\varphi - \hat{\delta}), \quad (\text{S5})$$

with $[\hat{\delta}, \hat{N}] = i$. The Hamiltonian of the weak link is [46]

$$\hat{H}_{\text{ABS}}(\phi) = \Delta \hat{U}(\phi) \left[\cos(\phi/2)\hat{\sigma}_3 + \sqrt{1-T}\sin(\phi/2)\hat{\sigma}_2 \right] \hat{U}^\dagger(\phi), \quad (\text{S6})$$

with $\hat{U}(\phi) = \exp(-i\sqrt{1-T}\hat{\sigma}_1\phi/4)$. Here $\hat{\sigma}_2$ and $\hat{\sigma}_3$ are two Pauli matrices which act on a space formed by the ground state of the weak link and an excited state with a pair of quasiparticles in the weak link. By expanding the product above, the Hamiltonian can be put in the form $\hat{H}_{\text{ABS}}(\phi) = V_2(\phi)\hat{\sigma}_2 + V_3(\phi)\hat{\sigma}_3$. The two functions V_2 and V_3 are:

$$V_2(\phi) = \Delta \sqrt{1-T} \sin(\phi/2) \cos(\sqrt{1-T}\phi/2) - \Delta \cos(\phi/2) \sin(\sqrt{1-T}\phi/2), \quad (\text{S7})$$

$$V_3(\phi) = \Delta \sqrt{1-T} \sin(\phi/2) \sin(\sqrt{1-T}\phi/2) + \Delta \cos(\phi/2) \cos(\sqrt{1-T}\phi/2), \quad (\text{S8})$$

We introduce the ground ($|g\rangle$) and excited states ($|e\rangle$) of the weak link in the presence of an equilibrium phase difference,

$$\hat{H}_{\text{ABS}}(\phi)|g\rangle = -E_{\text{ABS}}(\phi)|g\rangle, \quad (\text{S9a})$$

$$\hat{H}_{\text{ABS}}(\phi)|e\rangle = +E_{\text{ABS}}(\phi)|e\rangle, \quad (\text{S9b})$$

where $E_{\text{ABS}}(\phi)$ is given in Eq. (1) of the main text. In the basis $|\pm\rangle$ of eigenstates of $\hat{\sigma}_3$, $\hat{\sigma}_3|\pm\rangle = \pm|\pm\rangle$, they are given by

$$|g\rangle = c_{g+}(\phi)|+\rangle + c_{g-}(\phi)|-\rangle, \quad (\text{S10a})$$

$$|e\rangle = c_{e+}(\phi)|+\rangle + c_{e-}(\phi)|-\rangle, \quad (\text{S10b})$$

with the coefficients

$$c_{g+}(\phi) = i \frac{E_A(\phi) - V_3(\phi)}{\sqrt{2E_A(\phi)[E_A(\phi) - V_3(\phi)]}}, \quad c_{g-}(\phi) = \frac{V_2(\phi)}{\sqrt{2E_A(\phi)[E_A(\phi) - V_3(\phi)]}}, \quad (\text{S11a})$$

$$c_{e+}(\phi) = -i \frac{E_A(\phi) + V_3(\phi)}{\sqrt{2E_A(\phi)[E_A(\phi) - V_3(\phi)]}}, \quad c_{e-}(\phi) = \frac{V_2(\phi)}{\sqrt{2E_A(\phi)[E_A(\phi) + V_3(\phi)]}}. \quad (\text{S11b})$$

The coefficients are normalized:

$$|c_{g+}(\phi)|^2 + |c_{g-}(\phi)|^2 = |c_{e+}(\phi)|^2 + |c_{e-}(\phi)|^2 = 1. \quad (\text{S12})$$

To find the resonant frequencies of the hybrid SQUID, we solve the eigenvalue problem $\hat{H}|\Psi\rangle = E|\Psi\rangle$ numerically. We adopt the basis $|\delta, \pm\rangle \equiv |\delta\rangle \otimes |\pm\rangle$ for the joint eigenstates of the $\hat{\delta}$ and $\hat{\sigma}_3$ operators: $\hat{\delta}\hat{\sigma}_3|\delta, \pm\rangle = (\hat{\delta}|\delta\rangle) \otimes (\hat{\sigma}_3|\pm\rangle) = \pm\delta|\delta, \pm\rangle$. For the numerical solution, we use a truncated Hilbert space where the phase interval $[-\pi, \pi)$ is restricted to M discrete points, with lattice spacing $2\pi/M$. A complete basis of the truncated Hilbert space is given by the $2M$ vectors $|\delta_k\rangle \otimes |\pm\rangle$ with $\delta_k = 2\pi k/M$ ($k = 0, \pm 1, \pm 2, \dots, \pm(M-1)/2$), and $|\pm\rangle$ the eigenvector of $\hat{\sigma}_3$. The Hamiltonian is thus represented as a $2M \times 2M$ matrix in this basis and diagonalized numerically. We choose the parameter M large enough to guarantee convergence of the eigenvalues.

Once the spectrum is known, we use the transition frequencies from the ground state, $\omega_n = E_n - E_{\text{GS}}$, to do a least-square fit to the experimental data. The details of the numerical procedure are listed in the Jupyter notebooks available at [48].

Once an eigenstate $|\Psi\rangle$ is determined numerically, we represent its two-component wavefunction in the basis of the weak link eigenstates $\{|g\rangle, |e\rangle\}$ from Eq. (S10), evaluated at $\phi = \varphi$:

$$|\Psi\rangle = \sum_{\delta} \sum_{\sigma=g,e} \Psi(\delta, \sigma) |\delta, \sigma\rangle, \quad \Psi(\delta, \sigma) = \langle \delta, \sigma | \Psi \rangle, \quad (\text{S13})$$

where

$$|\delta, \sigma\rangle = |\delta\rangle \otimes (c_{\sigma+}(\varphi)|+\rangle + c_{\sigma-}(\varphi)|-\rangle). \quad (\text{S14})$$

The probability densities $|\Psi(\delta, \sigma)|^2$ plotted in Fig. 3b and Fig. S7b allow us to evaluate at a glance whether the eigenstate $|\Psi\rangle$ has a large overlap with the excited state $\sigma = |e\rangle$ of the (decoupled) weak link.

Finally, in Fig. 3c we show the numerical prediction for the visibility of the ABS transition as a function of the phase bias, ϕ . The visibility is determined by the absolute square of current operator matrix element $\langle GS | \hat{J}(\varphi) | \Psi \rangle$ between the ground state $|GS\rangle$ and the excited state $|\Psi\rangle$ of \hat{H} corresponding to the ABS transition. The current operator is [47]

$$\hat{J}(\varphi) = E_J \sin(\hat{\delta}) + \frac{\partial H_{\text{ABS}}(\varphi - \hat{\delta})}{\partial \hat{\delta}}. \quad (\text{S15})$$

Equilibrium phase drop

In the main text, we have often assumed that the equilibrium phase drop across the weak link, ϕ , is close to the total applied phase, $\phi \approx \varphi$. Here, we verify this assumption by calculating the equilibrium phase drop of the hybrid SQUID model we presented in the previous section.

Since $\phi = \varphi - \delta$, (see Eq. (S5)), it is sufficient to show that the equilibrium phase drop $\delta \equiv \langle GS | \hat{\delta} | GS \rangle$ across the tunnel junction is small. δ is given by the position where the ground state Josephson energy of Eq. (S5) is minimal for $E_C = 0$. From this condition, after taking a derivative of the Josephson energy, we obtain the following transcendental equation for δ :

$$E_J \sin(\delta) + \frac{\Delta T}{4} \frac{\sin(\delta - \varphi)}{\sqrt{1 - T \sin^2[(\varphi - \delta)/2]}} = 0. \quad (\text{S16})$$

FIG. S9. **Equilibrium phase drop δ across the tunnel junction.** The black line is given by Eq. (S17), the red line by the numerical solution of Eq. (S16). In both cases, we use the same circuit parameters as in Fig. 3a of the main text: $\Delta = 122 \mu\text{eV}$, $T = 0.57$, $E_J = 165 \mu\text{eV}$.

We note that the above expression defines a zero net current through the hybrid SQUID with the two arms hosting the same supercurrent. For $E_J \gg \Delta T/4$, a good approximate solution is given by

$$\delta \approx \frac{\Delta T}{4E_J} \frac{\sin(\varphi)}{\sqrt{1 - T \sin^2(\varphi/2)}}. \quad (\text{S17})$$

up to quadratic corrections in $(\Delta T/E_J)$. In Fig. S9 we show that for the parameters used in Fig. 3a, this approximate solution is very close to the exact, numerical one. Both exhibit a sinusoidal behavior with a maximum $\delta \approx 0.12$ at $\varphi \approx \pi/2$. This confirms that the phase drop across the weak link, $\phi = \varphi - \delta$, remains very close to the applied phase φ everywhere. In particular, ϕ is exactly equal to φ at $\varphi = n\pi$, where n is integer.

Andreev bound states in a proximitized Rashba nanowire in a parallel magnetic field

In this Section, we introduce the model used to describe the behavior of ABS as a function of the magnetic field B . We start from the standard Bogoliubov-de Gennes (BdG) Hamiltonian of a Rashba quantum wire with proximitized s -wave superconductivity and an external Zeeman field [49, 50]:

$$H_{\text{BdG}} = - \left(\frac{\partial_x^2}{2m} - E_F \right) \tau_z - i \alpha \partial_x s_z \tau_z + E_Z s_x + \Delta e^{i\phi \theta(x) \tau_z} \tau_x + V \delta(x) \tau_z. \quad (\text{S18})$$

Here, the two sets of Pauli matrices $\tau_{x,y,z}$ and $s_{x,y,z}$ act in the Nambu and spin spaces, respectively; $m = 0.023m_e$ is the effective mass in InAs [51], α is the Rashba spin-orbit coupling strength which defines $E_{\text{SO}} = m\alpha^2/2$. $E_Z = \frac{1}{2}g\mu_B B$ is the Zeeman energy, Δ is the proximity induced gap and θ is the Heaviside step function. The Fermi level E_F is measured from the middle of the Zeeman gap in the normal state band dispersion, see Fig. S11. Note that starting with Eq. (S18) we set $\hbar = 1$. The superconducting phase difference between the left lead ($x < 0$) and the right lead ($x > 0$) is denoted by ϕ . The last term of Eq. (S18) models a short-range scatterer at $x = 0$, accounting for the finite channel transmission.

We seek bound state solutions of the the BdG equations,

$$H_{\text{BdG}} \Psi(x) = E \Psi(x), \quad (\text{S19})$$

at energies $|E| < \Delta$. We will consider in particular two opposite regimes: (a) $E_F \gg E_{\text{SO}}, E_Z, \Delta$ and (b) $E_F = 0$, see the two insets in the corresponding panels of Fig. S11. In order to find bound state solutions we proceed as follows:

1. We linearize the BdG equations for the homogeneous system ($V = 0, \phi = 0$) around $E = E_F$. In this way, we obtain two effective low-energy Hamiltonians, $H_{\text{eff}}^{(a)}$ and $H_{\text{eff}}^{(b)}$, which are linear in the spatial derivative. They can be written as:

$$H_{\text{eff}}^{(a)} = -iv \partial_x \tau_z \sigma_z - vq_0 \tau_z \rho_z + \frac{\Delta \alpha k_F}{vq_0} \tau_x \sigma_z + \frac{\Delta E_Z}{vq_0} \tau_y \rho_y, \quad (\text{S20a})$$

$$H_{\text{eff}}^{(b)} = -i\alpha \partial_x \tau_z \sigma_z + \Delta \tau_x + \frac{1}{2} E_Z \sigma_z (1 - \rho_z). \quad (\text{S20b})$$

We now have three sets of Pauli matrices: $\tau_{x,y,z}$ (Nambu space), $\rho_{x,y,z}$ [distinguishing the inner/outer propagating modes, and replacing the spin matrices $s_{x,y,z}$ of Eq. (S18)], and $\sigma_{x,y,z}$ (distinguishing left- and right-moving modes, and not to be confused with the σ matrices used in the previous Section). For regime (a), we have also introduced the Fermi momentum $k_F = \sqrt{2mE_F}$, the Fermi velocity $v = k_F/m$ and the energy difference $vq_0 = \sqrt{\alpha^2 k_F^2 + E_Z^2}$ between the two helical bands at the Fermi momentum. Note that, in the regime (b) where $E_F = 0$, the linearization requires $E_{\text{SO}} \gg \Delta, E_Z$, so it corresponds to the limit of strong spin-orbit coupling.

2. Using Eq. (S18), we compute the transfer matrix \mathcal{T} of the junction in the normal state ($\Delta = 0$), at energy $E = E_F$. The transfer matrix gives a linear relation between the plane-wave coefficients of the general solution on the left and right hand sides of the weak link. In computing \mathcal{T} , we neglect all terms $\propto E_F^{-1}$ in regime (a). In regime (b), the transfer matrix is computed for $E_Z = 0$, since the effect of magnetic field on scattering can be neglected to due the small dwell time in the short junction. At $E_Z = 0$, the transfer matrix depends on the single real parameter T , the transmission probability of the junction. The latter is given by $T = 4k_F^2/(4k_F^2 + V^2)$ in regime (a), and $T = 1/(1 + V^2/\alpha^2)$ in regime (b).
3. Using the transfer matrix \mathcal{T} as the boundary condition at $x = 0$ for the linearized BdG equations, we obtain the following bound state equation for E :

$$\det \left[1 - G(E) \tau_z \sigma_z \left(e^{-i\phi \tau_z / 2} \mathcal{T} - 1 \right) \right] = 0, \quad (\text{S21})$$

where $G(E)$ is the integrated Green's function,

$$G(E) = v \int \frac{dq}{2\pi i} e^{-iq \cdot 0} [H_{\text{eff}}(q) - E]^{-1}, \quad (\text{S22})$$

and $H_{\text{eff}}(q)$ is the Fourier transform of either of the linearized Hamiltonians of Eq. (S20). [In regime (b), v must be replaced by α in the expression for $G(E)$]. In deriving the bound state equation, we have neglected the energy dependence of the transfer matrix, which is appropriate in the short junction limit. In regime (b), this also requires that the length of the junction is shorter than α/E_Z , so that we can neglect resonant effects associated with normal-state quasi-bound states in the Zeeman gap, which would lead to a strong energy dependence of the transmission [52]. Eq. (S21) is analogous to the bound state equation for the ABS derived in Ref. [53], except that it is formulated in terms of the transfer matrix of the weak link, rather than its scattering matrix. Unlike its counterpart, Eq. (S21) incorporates the effect of the magnetic field in the superconducting leads. It is thus appropriate to study the effect of a magnetic field on the ABS in the limit of uniform penetration of the field in the superconductor.

4. After performing the integral for $G(E)$, the roots of Eq. (S21) can be determined numerically. For the two regimes, this leads to the typical behavior of the ABS shown in Fig. S11 against the experimental data. As mentioned in the main text and discussed below, we find a better agreement with the experimental data for regime (a).

From $G(E)$, we can also compute the proximity-induced gap of the continuous spectrum $\Delta(B)$: $\Delta(B)$ is the minimum value of E such that the poles of $G(E)$ touch the real axis in the complex plane [of course, $\Delta(B)$ can also be found by minimizing the dispersion relation obtained by diagonalizing Eq. (S20) in momentum space]. In regime

(a), the relevant spectral gap is always at the finite momentum, so the behavior of $\Delta(B)$ depends on the strength of the spin-orbit coupling, as shown in Fig. S10. Two features are evident from the figure.

First, with increasing spin-orbit coupling, the linear behavior $\Delta(0) - \Delta(B) \propto B$ changes to a quadratic suppression $\Delta(0) - \Delta(B) \propto B^2$ for small B . This is due to the vanishing first-order matrix elements of the Zeeman interaction, due to the removal of the spin degeneracy of finite-momentum states by the spin-orbit interaction. Secondly, the proximity-induced gap $\Delta(B)$ never closes – as long as the superconductivity in the aluminium shell is present – because spin-orbit interaction competes with the Zeeman effect and prevents the complete spin polarization of the electrons. These two facts explain the behavior of $\Delta(B)$ shown in Fig. 4b of the main text. In regime (b) with $E_F = 0$, which is extensively discussed in the literature of Majorana bound states, $\Delta(0) - \Delta(B) \propto B$ due to the Zeeman-induced suppression of the gap for states at zero momentum (where spin-orbit is not effective).

An in-depth theoretical study of Eq. (S21), including a detailed analysis of its roots at finite magnetic fields and the code used in the numerical solution, is in preparation. It will also be interesting to extend the current model beyond the linearization to allow the calculation of the spectrum at arbitrary values of E_F .

FIG. S10. **The effect of the spin-orbit interaction and Zeeman field on the induced superconducting gap.** The lack of spin-orbit interaction leads to a linear decrease of $\Delta(B)$ (black line), which becomes parabolic in the limit of $\sqrt{E_{SO} E_F} \gg E_Z = \frac{1}{2} g \mu_B B$ (blue and green lines). The green line corresponds to the best fit to the experimental data shown in the main text.

Orbital field

Because a quadratic suppression of $\Delta(B)$ and the ABS energies may also be due to the orbital effect of the magnetic field, without invoking spin-orbit interaction, it is important to compare the data with this scenario. In a simple model which includes orbital and Zeeman effect, the field-dependence of the Andreev bound states may be written down as follows:

$$E_{\text{ABS},\pm}^{(\text{orb})}(\phi, B) = \Delta(1 - B^2/B_*^2) \sqrt{1 - T \sin^2(\phi/2)} \pm (1/2)g\mu_B B. \quad (\text{S23})$$

Here, $B_* \sim \Phi_0/A$ is the magnetic field scale which governs the suppression of the proximity-induced gap due to the orbital field, A is the cross-section of the nanowire and $\Phi_0 = h/2e$. In writing Eq. (S23), we have neglected the effect of the orbital field on the scattering at the junction. This should be a good approximation as long as the junction is modeled by a $\delta(x)$ potential with no dependence on the radial coordinate of the nanowire. Thus, essentially, the phase dependent part of the Andreev bound state energies can be obtained by replacing Δ with $\Delta(1 - B^2/B_*^2)$ in Eq. (1) of the main text. In the absence of spin-orbit coupling, the Zeeman term enters additively in Eq. (S23).

Using Eq. (S23), we can perform a fit to the experimental data to determine the optimal value $B_* = 400 \pm 2$ mT. Note that the fit is insensitive to the value of g , since g drops out from the sum $E_{\text{ABS},+}^{(\text{orb})} + E_{\text{ABS},-}^{(\text{orb})}$. However, Eq. (S23) predicts the occurrence of a fermion parity-switch at a field $B_{\text{sw}} < B_*$ given by the condition $E_{\text{ABS},-}^{(\text{orb})}(\phi, B_{\text{sw}}) = 0$. From this condition, and assuming the knowledge of both B_{sw} and B_* , the g -factor can then be deduced by inverting Eq. (S23) at $\phi = \pi$,

$$g = \frac{\Delta \sqrt{1-T}}{\mu_B B_{\text{sw}}} (1 - B_{\text{sw}}^2/B_*^2) \quad (\text{S24})$$

The occurrence of this fermion-parity switch must be accompanied by a drastic disappearance of the ABS transition [54]. In the experiment, such disappearance can be excluded up to at least 300 mT. Therefore, by requiring that $B_{\text{sw}} > 300$ mT and using the values quoted in the main text for all other parameters, we obtain an upper bound of g ,

$$|g| < 5.08 \quad (\text{S25})$$

In Fig. S11c we plot the energy spectrum resulting from Eq. (S23), which includes only the orbital and Zeeman effects. The black line in Fig. S11c represents the edge of the continuous spectrum for states with spin down, $\Delta(B) = \Delta(1 - B^2/B_*^2) - \frac{1}{2}g\mu_B B$. In Fig. S11c, we choose $g = 5$, close to the upper bound of Eq. (S25). The inclusion of a weak spin-orbit coupling in the model would not affect the curvature of $\Delta(B)$ and $E_{\text{ABS}}^{(\text{orb}),\pm}(B)$ at small fields $g\mu_B B \ll \Delta$ (see the blue curve in Fig. S10): the curvature would still be entirely dictated by the orbital effect. As mentioned in the main text, the Andreev level and the continuum cross at a value of the field B_{cross} such that $E_{\text{ABS}}^{(\text{orb}),+}(B_{\text{cross}}) = \Delta(B_{\text{cross}})$. For $B_* = 400$ mT and $g = 5$, the crossing happens at $B_{\text{cross}} \approx 150$ mT, see Fig. S11c. However, the inclusion of a weak spin-orbit coupling prevents the level crossing, causing the Andreev level to bend below the edge of the continuum. As a consequence, the transition energy $E_{\text{tot}}(B)$ decreases sharply at $B > B_{\text{cross}}$, in contrast with its behavior in the absence of spin-orbit coupling (compare the dashed and dotted lines in Fig. S11c). The behavior of $E_{\text{tot}}(B)$ in the presence of weak spin-orbit coupling clearly disagrees with the experimental data in the field range $150 \text{ mT} < B < 300 \text{ mT}$.

The considerations above motivate the approximation used in the main text, where we attribute the quadratic suppression of $E_{\text{tot}}(B)$ to the joint effect of spin-orbit and Zeeman couplings; the orbital effect does not play a dominant role in the observed dispersion.

Fits to the data

We have presented three different scenarios that can be used to interpret the magnetic field dependence of the ABS transition energies. We have fitted all three models to the entire data set available, consisting of a flux bias sweep of the ABS spectra at six different magnetic fields ($B = 50, 75, 100, 150, 200$ and 300 mT). For each flux bias at which it was visible, we have extracted the position of the ABS transition. For each value of B we attributed to all the data points an error bar corresponding to the half-width at half-maximum of the ABS peak at $\varphi = \pi$, neglecting for simplicity the flux variation of the width. The total dataset consisted of more than 300 datapoints. We then performed a least-square fit to the ABS transition energies predicted by the three different models. The results are illustrated in Fig. S11.

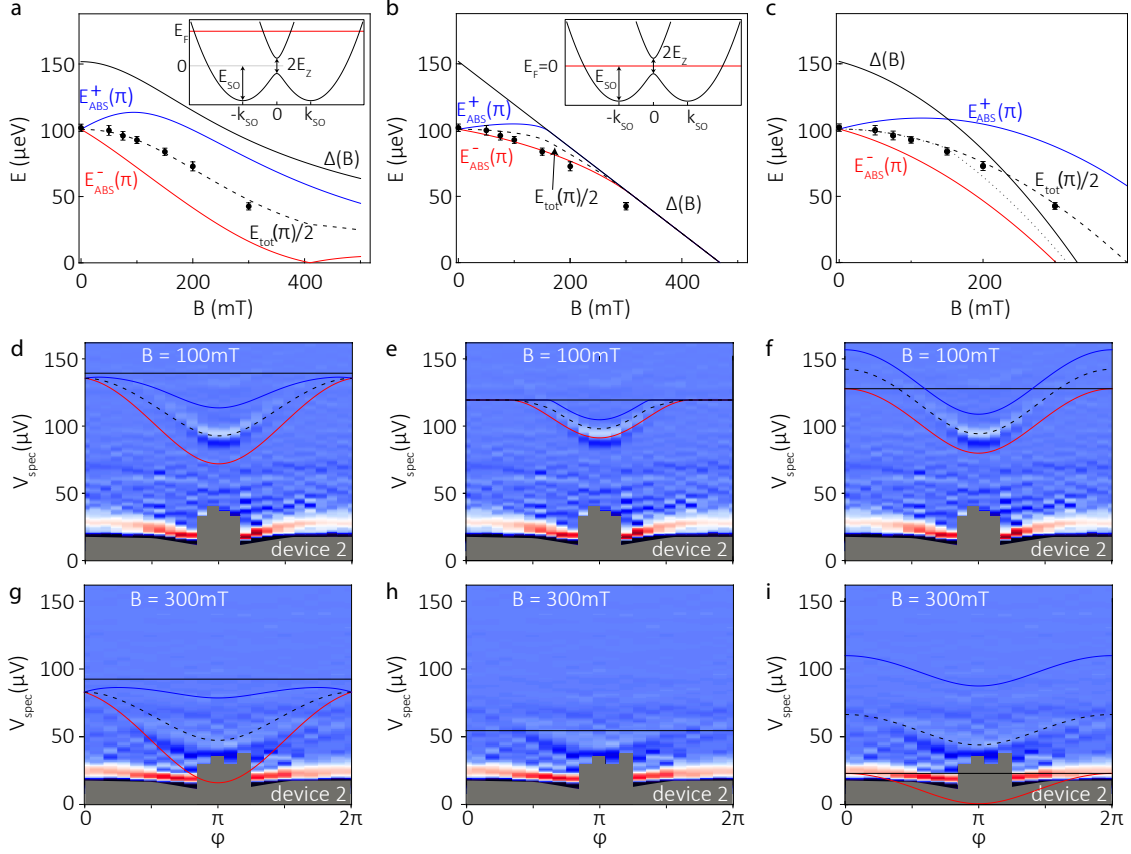

FIG. S11. **The magnetic field dependence of ABS in high and low Fermi level regimes and for orbital magnetic field.** The top row shows the evolution of the spin-split Andreev levels $E_{\text{ABS}}^{\pm}(B)$ (blue and red lines), the transition energy $E_{\text{tot}}(B) = E_{\text{ABS}}^{+}(B) + E_{\text{ABS}}^{-}(B)$ (dashed line) at $\varphi = \pi$ and the proximity-induced gap $\Delta(B)$ versus the magnetic field B . The theoretical curves for E_{tot} are compared against the experimental data (black dots). The three panels correspond to the three different theoretical models described in the text: high Fermi level (a), low Fermi level (b), and a model without spin-orbit coupling but only orbital and Zeeman effects of the field (c). For the latter, the dotted line in panel (c) depicts the qualitative behavior of E_{tot} if a weak-spin orbit coupling is included in the model. The middle and the bottom row show the resulting dispersion of the Andreev levels as a function of φ for the three different theoretical models, displayed on top of the measured spectrum at $B = 100$ mT and $B = 300$ mT, respectively. In each row, all three columns feature the same experimental dataset. The global fit parameters for the left column are $g = 14.7 \pm 0.6$ and $\sqrt{E_{\text{SO}}E_F}/\Delta = 0.32 \pm 0.02$. The middle column is evaluated with a single fit parameter $g = 11.2 \pm 0.1$. Note the lack of dispersion in panel (h), due to the merging of the Andreev bound states with the continuum, which causes all the lines to fall on top of each other. In the right column we use the best-fit value $B_* = 400 \pm 2$ mT and $g = 5$, the latter imposed by the lower bound on the parity switching field $B_{\text{sw}} > 300$ mT, where $E_{\text{ABS}}^{-}(\pi) = 0$.
