Abstract. Accurate lidar-based measurements of cloud optical extinction, even though perhaps limited to the cloud base region, are useful. Arguably, more advanced lidar techniques (e.g. Raman) should be applied for this purpose. However, simpler polarisation and backscatter lidars offer a number of practical advantages (e.g. better resolution and more continuous and numerous time series). In this paper, we present a backscatter lidar signal inversion method for the retrieval of the cloud optical extinction in the cloud base region. Though a numerically stable method for inverting lidar signals using a far-end boundary value solution has been demonstrated earlier and may be considered as being well established (i.e. the Klett inversion), the application to high-extinction clouds remains problematic. This is due to the inhomogeneous nature of real clouds, the finite range resolution of many practical lidar systems, and multiple scattering effects. We use an inversion scheme, where a backscatter lidar signal is inverted based on the estimated value of cloud extinction at the far end of the cloud, and apply a correction for multiple scattering within the cloud and a range resolution correction. By applying our technique to the inversion of synthetic lidar data, we show that, for a retrieval of up to 90 m from the cloud base, it is possible to obtain the cloud optical extinction within the cloud with an error better than 5%. In relative terms, the accuracy of the method is smaller at the cloud base but improves with the range within the cloud until 45 m and deteriorates slightly until reaching 90 m from the cloud base.

1 Introduction

Lidar has been used to probe the atmosphere ever since 1960 (e.g. Collis, 1966; Fiocco and Smullin, 1963). Lidar measurements facilitate characterisation of the atmosphere and have many different applications, including determining the properties of aerosols (Müller et al., 1998) and clouds (Turner, 2005).

Lidars possess a unique ability to observe the optical properties of clouds, such as the cloud extinction coefficient (α). Through an inversion of the backscattered power received by a lidar system, an estimate of the cloud extinction coefficient can be retrieved (Klett, 1981). This optical property of the cloud can be linked to the cloud's microphysical properties (Kokhanovsky, 2004). Although lidar can only penetrate a small part of a cloud, typically 100 to 300 m from the cloud base, the cloud base region is of strong interest for studies concerned with cloud formation and aerosol–cloud interactions (McComiskey and Feingold, 2012).

Despite the long history of lidar measurements and the vast amount of data available, very few quantitative evaluations of the cloud optical extinction retrieval accuracy under realistic conditions exist (e.g. Carnuth and Reiter, 1986; Roca-denbosch et al., 1998). Lidar signal inversion in realistic conditions is more difficult due to the effects of finite lidar range resolution and multiple scattering occurring within the cloud.

In this paper, we present a procedure to retrieve the cloud optical extinction coefficient, using a single field of view (FOV) depolarisation lidar. We use the Klett solution (Klett, 1981) with the inclusion of a multiple scattering correction

(Hu et al., 2006; Roy and Cao, 2010) and an explicit treatment of the molecular and cloud contributions to the returned signal (Fernald, 1984). We demonstrate, using synthetic lidar signals generated using a Monte Carlo RT model fed with large eddy simulation (LES) fields, that useful extinction profiles can be retrieved using simple elastic polarisation lidars.

The outline of the paper is as follows. In Sect. 2 we present background material. In Sect. 3 we give a brief description of the EarthCARE Simulator (ECSIM) and the scenes created for this investigation. Section 4 presents the results of the inversion, discusses the issues related to conducting accurate inversions, and presents our methodology to address them. We conclude the paper with a summary of the findings and an outlook of possible applications.

2 Lidar signal inversion

The single-scattering lidar equation for a two-component atmosphere (cloud and molecular) can be defined as follows:

$$P(z) = \frac{C_{\text{lid}}}{z^2} (\beta_{c,\pi}(z) + \beta_{m,\pi}(z)) e^{-2\int_0^z (\alpha_c(z') + \alpha_m(z')) dz'}, \quad (1)$$

where z is the altitude, $P(z)$ is the received power as a function of altitude, C_{lid} is the lidar calibration constant, β_π is the atmospheric backscatter coefficient, α is the atmospheric extinction coefficient, and the “c” and “m” subscripts distinguish between cloud and molecular backscatter and extinction (Fernald, 1984). As the Klett solution applies strictly to a one-component atmosphere, we introduce α' and P' in order to account for the mixed contributions from cloud and/or aerosol and molecular scattering (Fernald, 1984).

If we define the following:

$$\alpha'(z) = \alpha_c(z) + S(z)\beta_{m,\pi}(z), \quad (2)$$

where S is the cloud extinction-to-backscatter ratio ($S = \alpha_c(z)/\beta_\pi(z)$), then, in the following:

$$P'(z) = SP(z)e^{2\int_0^z (\alpha_m(z')) dz'} e^{-2\int_0^z (S\beta_m(z')) dz'}. \quad (3)$$

Thus, Eq. (1) can be recast as follows:

$$P'(z) = \frac{C_{\text{lid}}}{S(z)z^2} \alpha'(z) e^{(-2\int_0^z \alpha'(z') dz')}, \quad (4)$$

which has the general form of the single-component lidar equation and has a well-known solution form (Klett, 1981).

In order to calculate the two-component transformed optical cloud extinction coefficient, α' , we invert Eq. (1) following the analytical solution to the single-scattering lidar equation proposed by Klett (1981).

$$\alpha'(z) = \frac{P'(z)z^2}{\frac{P'(z_0)z_0^2}{\alpha'_0} + 2\int_z^{z_0} (P'(z')z'^2) dz'}, \quad (5)$$

where, in the following:

$$\alpha'_0(z_0) = \alpha_c(z_0) + S\beta_{m,\pi}(z_0). \quad (6)$$

α_0 is the extinction coefficient at a reference height z_0 , and S is assumed to be range-independent within the cloud, and for water clouds and wavelengths in the range from 200 to 1064 nm, it is around 16 sr (Yorks et al., 2011). Following the method established by Klett (1981) and later Fernald (1984), we estimate the value of the extinction coefficient at the far end of the range interval to retrieve the full profile of the extinction coefficient. This method was tested for cloudy and foggy conditions and proved appropriate for retrieving the extinction values. It shows a small dependence on the estimated extinction boundary value (α'_0) when the optical thickness of the range interval is increasing (Klett, 1985; Carnuth and Reiter, 1986).

Although the principle of this method of lidar signal inversion is straightforward, there are a number of issues that must be addressed to ensure accurate results. Section 4.1 outlines these difficulties and presents possible ways of overcoming them. In this work, we make use of simulated lidar signals for which the true extinction profiles are known. The simulations include the effects of realistic cloud structure and the effects of finite lidar range resolution and lidar multiple scattering. Each of these factors must be accounted for before accurate results can be produced by applying Eq. (5). Each of these issues is addressed in turn. In Sect. 4.1.3, we discuss the effects of finite range resolution, and in Sect. 4.1.2, the approach to accounting for multiple scatterings is discussed.

3 ECSIM simulations

To evaluate the retrieval of the cloud extinction, we use synthetic signals produced using the EarthCARE simulator (ECSIM). ECSIM is a tool to simulate the measurements of four instruments, namely the 94 GHz cloud profiling radar, the high spectral resolution lidar at 353 nm, the multi-spectral imager, and the broadband radiometer (Donovan et al., 2015). The lidar model takes into account polarisation, multiple scattering, and the effects of finite lidar range resolution. For the simulations carried out in this work, the lidar wavelength was 355 nm, the field of view was 2 mrad, the laser divergence 0.1 mrad, and the range resolution was 15 m. The ECSIM radar model was also used in this paper in an ancillary role. To retrieve information about the cloud extinction, we only need information from lidar. However, information from radar can be used for a further analysis of the scene. Radar can add the ability to identify regions of drizzle. It can also penetrate through a liquid water cloud and, hence, is useful for establishing the height of the cloud top.

To create the scene used in this work, a liquid water content (LWC) field was generated by a LES and introduced to ECSIM. The LES case used corresponded to one from the FIRE campaign (Albrecht et al., 1988). The ECSIM sim-

ulation specifically used an output from the Dutch Atmospheric LES model (DALES; Heus et al., 2010). DALES utilises a two-moment bulk scheme to model precipitation (Khairoutdinov and Kogan, 2000), where condensed water is qualified as either cloud water or precipitation, and the number density of cloud droplets is prescribed. The ECSIM scene is created based on a snapshot of parameters extracted from DALES. Those parameters include temperature, pressure, non-precipitable cloud water, precipitation water content, and precipitation droplet number density. Furthermore, an explicit droplet size distribution (DSD) is needed to create an ECSIM scene. As DALES does not provide DSDs, imposed DSDs were used based on the DALES output. The precipitation mode DSD was based on the one from Khairoutdinov and Kogan (2000). The cloud mode DSDs were found by assuming modified gamma type distribution with a width parameter of 5 and assuming a constant cloud number density; the effective radius of the distributions was then calculated using the model LWC fields.

Figure 1 presents the cross section of the radar reflectivity factor and the attenuated backscatter coefficient of the used cloud scene. This cloud scene consists of 450 profiles of attenuated backscatter coefficient; all of those profiles were used in the analysis hereafter. We performed two simulations based on the same DALES output. One of the cloud scenes was made to simulate attenuated backscatter coefficient with the inclusion of single and multiple scattering effects (referred to as B_{MS} later in the text), and the second simulation was made for only the single scattering attenuated backscatter coefficient (referred to as B_{SS} later in the text). This allowed us to directly compare the impact of the multiple scattering on the retrieved values of the extinction coefficient and evaluate the correction for the multiple scattering presented in Sect. 4.1.2.

4 Inversion results

4.1 Difficulties in inversion steps

4.1.1 Defining the normalisation interval

In order to obtain a profile of the optical cloud extinction from lidar returns, we need to invert the received power (Eq. 1) into a cloud optical extinction coefficient, as explained in Sect. 2. Following the solution proposed by Klett (1985), it is necessary to define the range interval where the signal can be normalised. The value of extinction, α'_0 , is estimated at a certain height, z_0 , based on the slope of the least square straight line fitted to the curve $ATB = ATB(z)$. The value of α'_0 is calculated as follows:

$$\alpha'_0 = -\frac{1}{2} \frac{d \ln ATB}{dz}, \quad (7)$$

where ATB is the attenuated backscatter coefficient ($ATB(z) = P(z)z_2$), and dz is the range resolution. Figure 2

Figure 1. Cross section of the radar reflectivity factor (a) and attenuated backscatter coefficient (b) of the cloud scene produced with the ECSIM simulator. The magenta line indicates the estimate of the cloud base height, and the black line indicates the beginning of the normalisation interval.

presents the profile of the cloud optical extinction retrieved based on the slope method. It shows clearly that the slope method is not accurate at the cloud base, and the retrieved values come closer to the true extinction only at a certain height within the cloud. This is in accordance with a proposition by Klett (1981), who postulated that the normalisation height z_0 where the value of α'_0 is estimated should be located at the far end of the cloud. It should be noted that, in the approach presented in this paper, the cloud optical extinction obtained through the slope method is used only to retrieve the value of α'_0 and initiate the inversion.

Another important aspect in deciding on the height of the normalisation interval is the profile of the attenuated backscatter coefficient (ATB). In order to calculate α'_0 , ATB at the chosen height has to be still usable, meaning that the noise level cannot be too high. Figure 3 presents the signal profile with a marked normalisation interval. Note that the interval is above the peak of the signal and just before signal starts to be noisy or lost. In this study, we chose a threshold for the ATB usability in the normalisation interval at a signal-to-noise ratio (SNR) of 20. We tested the sensitivity of the inversion method to different values of SNR and found that values below 20 tend to influence the retrieval in the higher

Figure 2. Profile of the extinction coefficient retrieved based on the slope method (Eq. 7) and the true extinction profile calculated from ECSIM.

Figure 3. Profile of the ATB and boundaries of the normalisation interval.

parts of the cloud. The first four bins within the cloud (up to 60 m within the cloud) are only affected by a mean error increase of 3 %. If the SNR is below 20, then the normalisation interval has to be set at a lower height.

4.1.2 Correcting the multiple scattering

Measurements of water clouds by lidar backscatter always involve some contribution from multiple scattering. In this study, we use the multiple scattering correction based on the accumulated depolarisation ratio (δ_{acc}) introduced by Hu et al. (2006) and further demonstrated by Cao et al. (2009). Lidar multiple scattering occurring in water clouds can be linked to the depolarisation ratio. At 180° backscatter direction, the single scattering of spherical droplets retains the polarisation of the incident light. However, scattering at different scattering angles changes the polarisation state. For the liquid water clouds, the depolarisation of the signal can be attributed to the multiple scattering (Sassen and Petrilla, 1986).

Based on the above-described characteristics of water clouds and lidar backscatter, Hu et al. (2006) described a relation between the linear depolarisation of the backscatter signal and the fraction of multiple scattering present in that signal. Based on the Monte Carlo simulations of the multiple scattering signals for numerous scenarios and different fields of view, they derived the following relation:

$$A_S(z) = \frac{I_S(z)}{I_T(z)} \approx \frac{(1 - \delta_{acc}(z))^2}{(1 + \delta_{acc}(z))^2}, \quad (8)$$

where $I_S(z)$ is the integrated, range-corrected single scattering signal, and $I_T(z)$ is the integrated, range-corrected total scattering signal (single and multiple scattering). Both signals are integrated between the cloud boundaries, where the cloud base height is established based on the lidar measurements. We use the top of the normalisation interval instead of the cloud top, as measurements above that height are no longer relevant. $\delta_{acc}(z)$ is the accumulated depolarisation ratio. It can be calculated from the parallel and perpendicular components of the total backscattering signal as follows:

$$\delta_{acc}(z) = \frac{I_{T,\perp}(z)}{I_{T,\parallel}(z)}, \quad (9)$$

where $I_{T,\perp}(z)$ is the total integrated perpendicular backscattered signal, and $I_{T,\parallel}(z)$ is the total integrated parallel backscattered signal.

In order to calculate the signal corrected for the multiple scattering, in other words, the signal contributing only to the single scattering ATB_{SS} , we use the following formula:

$$ATB_{SS}(z) = A_S(z)ATB_{MS}(z) + I_T(z) \frac{dA_S}{dz}, \quad (10)$$

where A_S is the correction factor calculated from Eq. (8), ATB_{MS} is the total range corrected signal, the $I_T(z)$ is the integrated, range-corrected total scattering signal, and $\frac{dA_S}{dz}$ is the derivative of the correction factor from Eq. (8). The last term of Eq. (10) can be used to evaluate the depolarisation both in simulated and real conditions. The value of $\frac{dA_S}{dz}$ should always be negative within the cloud because more multiple scattering occurs higher within the cloud, and a

Figure 4. Profiles of the retrieved cloud optical extinction retrieved through an inversion of the signal with different corrections. The green line represents the true extinction calculated with the ECSIM. The black solid line represents the extinction profile retrieved without any corrections from the modelled single scattering attenuated backscatter. The dashed black line represents the extinction profile retrieved from the modelled single scattering attenuated backscatter with the resolution correction. The blue solid line represents the extinction profile retrieved without any corrections from the modelled multiple scattering attenuated backscatter. The dashed blue line represents the extinction profile retrieved from the modelled multiple scattering attenuated backscatter with the resolution correction. The red line represents the extinction profile retrieved from the modelled multiple scattering attenuated backscatter with the resolution and multiple scattering correction. The dashed cyan line indicates the beginning of the normalisation interval.

smaller part of the signal can be associated only with the single scattering.

Figure 4 presents samples of retrieved profiles with the correction for the multiple scattering (noted as MS correction) plotted against the cloud optical thickness (τ). It presents also the simulated data with the single scattering only (noted as SS) for comparison. It is expected that, by applying the multiple scattering correction, we can achieve results similar to the single scattering simulations. Applying the MS correction improves the accuracy greatly and minimises the error of the retrieved profiles (for more detailed information, see Table 2). Based on the data analysis performed for this paper, we can conclude that multiple scattering correction has a big impact on the accuracy of the retrieved cloud optical extinction.

4.1.3 Effects of the range resolution

The finite range resolution of the lidar signal is another factor that influences the final results of the inversion. The range resolution of lidar varies, depending on the system, and the larger it is, the higher its impact might be on the final inversion results. Problems with the resolution of lidar were mentioned before (Evans, 1984) but were never really studied, and no solution to the problem has been proposed so far.

The difficulty associated with the range resolution occurs since practical lidar data are always acquired at a finite resolution and, thus, must be interpreted using a discrete form of solution to the lidar equation. The continuous form of the Eq. (5) is often naively transformed into a discrete form, where the integration is transformed into a summation using, for example, the trapezoid rule, yielding the following:

$$\alpha'_i = \frac{P'_i z_i^2}{\frac{P'_{i_0} z_{i_0}^2}{\alpha'_0} + \left[P'_i z_i^2 \Delta z + 2 \sum_{i+1}^{i_0-1} P'_i z_i^2 \Delta z + P'_{i_0} z_{i_0}^2 \Delta z \right]}. \quad (11)$$

The above equation is valid for the case where $z_i < z_0$; if $z_i > z_0$, then the “+” in the denominator is replaced by a “−”, and the limits of the summation are swapped. Although this is a common practice when transforming continuous equation to discrete form in algorithms, it may not be sufficiently accurate. If the value of $\alpha' \Delta z$ is small enough, then the approximation by the use of the trapezoid rule is accurate, and the resulting value of α' corresponds to the bin midpoint. However, if that value is large, the applied approximation is not correct anymore. The detailed explanation of the calculations is presented in Appendix A.

Based on the calculations and using the midpoint of the bins, we define the resolution correction factors (IRES₁, IRES₂) and RES₂ as follows:

$$\text{IRES}_1(z_i) = \frac{e^{\alpha'(z_i)\Delta z} - 1}{e^{\alpha'(z_i)\Delta z} - e^{-\alpha'(z_i)\Delta z}}, \quad (12)$$

$$\text{IRES}_2(z_i) = \frac{1 - e^{-\alpha'(z_i)\Delta z}}{e^{\alpha'(z_i)\Delta z} - e^{-\alpha'(z_i)\Delta z}}, \quad (13)$$

and as follows:

$$\text{RES}_2(z_i) = \frac{2\alpha'(z_i)\Delta z}{e^{\alpha'(z_i)\Delta z} - e^{-\alpha'(z_i)\Delta z}}, \quad (14)$$

where $\alpha'(z)$ is the retrieved cloud optical extinction, and Δz is the height resolution.

IRES₂(z_i) is applied as a multiplicative correction to the first term within the square bracket within Eq. (11). IRES₂(z_i) is applied to the last term, while IRES₂(z_i) is applied as a factor to the numerator and the first term in the denominator.

As the corrections are functions of the extinction itself, in order to apply this correction factor, we need to perform the inversion in two steps. First, we invert the lidar signal

and apply the multiple scattering correction. The resulting optical cloud extinction (α) from the first inversion is used in the range resolution correction terms (Eqs. 12–14), and then the corrected signal is inverted again.

Figure 4 presents the retrieved profiles of α with the multiple scattering correction (denoted as MS) and with the multiple scattering correction, together with the range resolution correction (denoted as MS and RES). We observe that, while the MS correction on its own improves the retrieval greatly, after application of the RES correction, values of α are closer to the true value of the extinction coefficient. The importance of the resolution correction can be easily presented when we inverted the simulated single scattering signal (B_{SS} ; as mentioned in Sect. 3). Table 2 presents the error and accuracy of the inversion results (as described in Sect. 4.3).

4.2 Estimating cloud base height

Although it is not directly connected to the inversion procedure, an accurate estimation of the cloud base height is also a challenging problem in cloud observation. In this study, we use the peak of the lidar perpendicular signal to evaluate the cloud base height. Lidar power ($P(z)$; Eq. 1) from a depolarisation lidar can be divided into the parallel ($P(z)_{\parallel}$) and perpendicular power ($P(z)_{\perp}$). In every profile we find the peak of the perpendicular power ($P(z)_{\perp\max}$) and estimate the cloud base to be at the height where $P(z)$ is equal to or greater than $P(z)_{\perp\max}$ divided by 10. We found that this estimate predicts the height of cloud base with a good accuracy for the liquid water clouds. Figure 1 presents the radar reflectivity factor and the attenuated backscatter coefficient for the scene used in this study. Both panels present the estimate of the cloud base height marked with a magenta line. Examining the panel with the ATB, we see that our estimate is a good approximation.

4.3 Signal inversion error and accuracy

In this study, we use the ECSIM cloud scene to test the accuracy and estimate the error of the lidar signal inversion. The data set from ECSIM gives us information about the true value of optical extinction coefficient within the cloud. Thanks to that, we can calculate the percent error and the accuracy of the inversion method by comparing the retrieved value to the true (simulated) value of the optical extinction coefficient. For those calculations, we use the following formulas to estimate the percent error:

$$E_{B_{SS} \text{ or } B_{MS}} = \frac{\alpha_{\text{retrieved}} - \alpha_{\text{simulated}}}{\alpha_{\text{simulated}}} \times 100\%, \quad (15)$$

and the following formulas to estimate the accuracy:

$$A_{B_{SS} \text{ or } B_{MS}} = \frac{\alpha_{\text{retrieved}}}{\alpha_{\text{simulated}}} \times 100\%, \quad (16)$$

where the subscript B_{SS} is used when we are inverting the signal from the single scattering simulation, and the subscript

45.0	93.69 %	6.35 %	95.11 %	4.97 %
60.0	94.37 %	5.63 %	96.26 %	3.80 %
75.0	94.49 %	5.51 %	96.76 %	3.28 %
90.0	94.48 %	5.52 %	97.08 %	2.93 %

B_{MS} is used for the simulations from the multiple scattering simulations. For the whole data set, the mean values for each height above the cloud base are presented in Tables 1 and 2 for B_{SS} and B_{MS} , respectively.

As we indicated before, values retrieved at the cloud base (defined as being 0 m from the cloud base in Tables 1 and 2) are the ones with the biggest percent error. This stems from the difficulty in the signal inversion at very small values of cloud optical extinction. We observe a great improvement in the accuracy of the inversion further within the cloud. We present values of the inversion error and accuracy for the retrieval without any correction and for the retrieval only with the resolution correction ($A_{B_{MS} \text{ with RES}}$ and $E_{B_{MS} \text{ with RES}}$), with the multiple scattering correction ($A_{B_{MS} \text{ with MS}}$ and $E_{B_{MS} \text{ with MS}}$) or with both the multiple scattering and the resolution correction ($A_{B_{MS} \text{ with RES\&MS}}$ and $E_{B_{MS} \text{ with RES\&MS}}$).

For the results of the inversion of the B_{SS} signal, we tested how the resolution correction can improve the results of the retrieval. Table 1 presents the mean error and accuracy calculated at different levels within the cloud. We observed an increased impact of the resolution correction deeper within the cloud. At a distance of 45 to 90 m from the cloud base, the resolution correction almost doubles the accuracy. This is mostly due to an increase in the value of cloud optical extinction (α). As we explain in the Appendix A, the resolution correction is less relevant for small values of α . Inversion of the signal with the simulated multiple scattering (B_{MS}), and, thus, resembling actual measurements far more, is understandably less accurate. Table 1 presents the mean error and accuracy of the retrieved cloud optical extinction for different heights above the cloud base. Inversion without any correction had a mean error ranging from 40 % at cloud base to 26 % in the cloud. We observed that, with the resolution correction only, the error can be improved by up to 3 %. The correction for the multiple scattering has a much bigger impact; it improves the inversion error by around 35 % at the

cloud base and by 20 % higher within the cloud. By combining the resolution and multiple scattering correction, the error of the inversion can be improved to between 6 % at the cloud base and 3 %–4 % within the cloud. We observed that the inversion is most accurate between 30 and 60 m within the cloud. Figure 5 presents the cross section of the retrieval percent error of the cloud optical extinction for the inversion of simulated multiple scattering signal with the inclusion of the resolution and multiple scattering correction. The increase in the error above 60 m from the cloud base is mainly due to an underestimation of the value of the cloud optical extinction at the normalisation height (α_0).

The accuracy of the retrieval is connected to the cloud optical thickness. Figure 6 presents scatterplots of the retrieved values of α , with the multiple scattering and range resolution correction plotted against the modelled ones. The data are divided by the value of the optical thickness, τ , where, in the following:

$$\tau(z) = \int_0^h \alpha'(z) dz. \tag{17}$$

α is the cloud optical thickness, and h is cloud depth. Every panel includes an imposed red line which represents an equality between the modelled and retrieved values. We also used a colour scale, where the colour bar represents the value of cloud optical extinction at every point. The error (Eq. 15) and accuracy (Eq. 16) for each bin on the optical thickness are also presented. We observed that the inversion method works best for the values of τ between 0.6 and 1.05. The error for values of τ above 1.5 is higher, and the retrieved cloud optical extinction is underestimated. The probable cause of this behaviour of the retrieval is the loss of a signal with the increase in the cloud optical thickness. For the optical thickness below 0.6 and further below 0.15, the important factor influencing the accuracy of the retrieval is the estimation of the cloud base region.

Figure 5. Cross section of the cloud optical thickness (a) and retrieval percent error of the cloud optical extinction retrieved with the multiple scattering and range resolution correction (b). The magenta line in both panels represents the estimated height of the cloud base, and the black line is the beginning of the normalisation interval.

Figure 5 presents the cross section of the cloud optical thickness and the retrieval percent error. Here, again, we can clearly see that the percent error is highest close to the cloud base, ranging between 8 % and 15 %, and deeper within the cloud it rarely exceeds 7 %. This means that, when inverting the lidar signal, it is important to carefully examine the first range above the cloud base.

Figure 6. Scatterplots of the retrieved cloud optical extinction (with the multiple scattering and range resolution correction) versus the modelled cloud optical extinction from the ECSIM divided into panels depending on the value of the optical thickness. The red line is imposed and represents the equality between the modelled and retrieved values. The colour bar represents the value of the cloud optical thickness at each point. The error E_α (Eq. 15) and accuracy A_α (Eq. 16) for each bin of the optical thickness are also presented.

4.4 Impact of α'_0 estimation

Klett (1981) stated that the value of α'_0 does not influence the final results of the inversion much. In our study, we tested this statement by performing an inversion with the actual value of extinction at the normalisation height z_0 instead of the value calculated from the slope method (Eq. 7). The results of this inversion are presented in Table 3. The error for the inversion with the multiple scattering and resolution correction is improved by around 0.5 %. The error improvement is more significant for the values retrieved above 60 m from the cloud base. This is due to the underestimation of the value of α'_0 with the slope method (Fig. 2). We also tested the accuracy of the calculated α'_0 by comparing it to the actual value of α at the normalisation height z_0 . The mean accuracy of α'_0 for the whole data set was 95 %, with the minimum accuracy of 89 % and the maximum one of 112 %.

5 Conclusions

In this paper, we presented a method of lidar signal inversion for the retrieval of the cloud optical extinction in the cloud base region. This method was first presented by Klett (1981). We showed that, with the correction for the multiple scattering within the cloud and the resolution correc-

Table 3. Mean error and accuracy of the cloud optical thickness extinction retrieval for different heights above the cloud base. Data are retrieved by inverting simulated multiple scattering signal (B_{MS}) with both the resolution and the multiple scattering correction, with α_0 equal to the true extinction at the normalisation height z_0 (denoted as α_{true}) and, in the second case, with the α_0 estimate calculated from Eq. (7) (denoted as α_{slope}).

Distance from cloud base	$A_{B_{MS}}$ for α_{true}	$E_{B_{MS}}$ for α_{true}	$A_{B_{MS}}$ for α_{slope}	$E_{B_{MS}}$ for α_{slope}
0.0	98.71 %	5.77 %	98.94 %	5.72 %
15.0	97.79 %	4.77 %	98.03 %	4.69 %
30.0	98.55 %	3.06 %	98.94 %	2.98 %
45.0	99.74 %	2.52 %	100.27 %	2.47 %
60.0	97.30 %	3.50 %	98.20 %	2.97 %
75.0	97.48 %	3.72 %	98.84 %	2.92 %
90.0	96.37 %	4.66 %	98.12 %	3.24 %

tion, this method can be successfully used for the retrieval of the cloud optical extinction. Both those corrections are essential to improve the accuracy of the retrieved extinction profile and minimise the error. We presented the performance of the retrieval based on the synthetically created cloud scene, where responses of the lidar to specific cloud conditions were simulated. Even though in some cases the

cloud base was not varying much in height, the analysed data indicated that the signal inversion close to the cloud base (specifically at the range of the detected cloud base) is prone to error. The retrieval of the cloud optical extinction works better at higher values of the optical thickness. It is, therefore, our recommendation to use only data points located at least one gate range above the detected cloud base height. We also showed that the approximation of α'_0 calculated with the slope method can be used as an estimation of actual cloud optical extinction at the normalisation height. More importantly, improving the value of α'_0 by using the actual extinction at the normalisation height does not improve the retrieved values significantly if the correction for the multiple scattering and range resolution is implemented.

We showed that the inversion of the lidar signal with the proposed corrections yields a good estimate of the cloud extinction. Not only is this method fast but can also, because of the use of a standard backscatter depolarisation lidar, be applied to multiple systems and used operationally. Through a link between cloud microphysical properties and the optical extinction, this can provide a valuable data set to be used in the studies of cloud microphysics and impacts of clouds on the climate.

Appendix A: Derivation of the resolution correction

The difficulty associated with the range resolution occurs since practical lidar data are always acquired at a finite resolution and, thus, must be interpreted using a discrete form of the lidar equation. In high-extinction environments, the differences between, for example, the bin mean value and the bin mid values of the range-corrected signal ($P(z)z^2$) can become important and impact the accuracy of applying, for example, Eq. (5) (the specific case relevant to this work). If high accuracy is sought, then the effects of the finite lidar resolution must be accounted for in both the numerator and the second term of the denominator of Eq. (5).

As a preliminary step, we start by defining the scaled attenuated backscatter as follows:

$$B(z) = P(z)z^2 C_{\text{lid}}^{-1} S(z), \tag{A1}$$

where C_{lid} is the lidar constant, z is the range from the lidar, P is the measured power, and S is the extinction-to-backscatter ratio. For convenience in this Appendix, we consider the case of a one-component atmosphere. The extension to the two-component case follows trivially by replacing P by P' and α by α' .

A1 Resolution correction for the integral term

In terms of $B(z)$, an expression analogous to the integral in the denominator of Eq. (5) is as follows:

$$I(z) = \int_z^{z_0} B(z') dz'. \tag{A2}$$

In discrete form, this becomes the following:

$$I(z_i) = \int_{z_i}^{z_i + \frac{\Delta z}{2}} B(z') dz' + \sum_{j=i+1}^{j=i_0-1} \int_{z_j - \frac{\Delta z}{2}}^{z_j + \frac{\Delta z}{2}} B(z') dz' + \int_{z_0 - \frac{\Delta z}{2}}^{z_0} B(z') dz', \tag{A3}$$

where the z_i refers to the bin mid position of the i th range bin, and Δz is the (constant) range bin width. Here, the form is valid for $z_i < z_{i_0}$. For the case of $z_i > z_{i_0}$, the upper and lower limits of the summation are swapped, and the sign of the whole expression is switched.

With reference to Fig. A1, we can rewrite these expressions in terms of the discrete form of the scaled attenuated backscatter signal for one range gate B_i and the associated half-bin values $B_{i,1}$ and $B_{i,2}$.

$$I(z_i) = B_{i,1} + \sum_{j=i+1}^{j=i_0-1} B_j + B_{i_0,2}. \tag{A4}$$

Figure A1. Illustration of the relationship between the continuous lidar scaled attenuated backscatter (red line), the bin-integrated average B_i and the half-bin integrated average values ($B_{i,1}$, together with $B_{i,2}$) and the mid bin value $B_{Mid,i}$.

The definitions of the terms in Eq. (A4) can be readily discerned by comparison with Eq. (A3). Equation (A3) indicates that the accurate evaluation of Eq. (A2) involves the summation of the B_i terms and the leading and trailing half-bin terms (the $B_{i,1}$ and $B_{i,2}$ terms). The B_i terms pose no difficulty as they are directly related to the lidar measurement process in a natural manner (i.e. the lidar (ideally) operates by physically accumulating (in other words, integrating) the return signal between two discrete times corresponding to the range gate boundaries). However, evaluating the edge terms requires more development.

In order to evaluate the $B_{i,1}$ and $B_{i,2}$ terms and their relationship with B_i , we start with the single scattering lidar equation in continuous form, which, in terms of $B(z)$, can be written as follows:

$$B(z) = \alpha(z) e^{-2 \int_0^z \alpha(z') dz'}, \tag{A5}$$

where α is the optical extinction. In terms of the optical thickness (τ), Eq. (A5) can be written as follows:

$$B(z) = \frac{d\tau}{dz} e^{-2\tau(z)}. \tag{A6}$$

If we assume that α and S are constant within one range gate (this assumption is physically reasonable for fine range resolutions and is also compatible with the lidar model used to generate the simulations used in this work), then using Eq. (A6) B_i can be calculated as follows:

$$B_i = \int_{z_i - \frac{\Delta z}{2}}^{z_i + \frac{\Delta z}{2}} B(z') dz' = -\frac{1}{2} e^{-2\tau(z)} \Big|_{z_i - \frac{\Delta z}{2}}^{z_i + \frac{\Delta z}{2}} = \frac{1}{2} \left(e^{-2\tau(z_i - \frac{\Delta z}{2})} - e^{-2\tau(z_i + \frac{\Delta z}{2})} \right). \tag{A7}$$

In a similar fashion, $B_{1,i}$ and $B_{2,i}$ are as follows:

$$B_{i,1} = \int_{z_i - \frac{\Delta z}{2}}^{z_i} B(z') dz' = -\frac{1}{2} e^{-2\tau(z)} \Big|_{z_i - \frac{\Delta z}{2}}^{z_i} = \frac{1}{2} \left(e^{-2\tau(z_i)} - e^{-2\left(\tau(z_i - \frac{\Delta z}{2})\right)} \right), \tag{A8}$$

and as follows:

$$B_{i,2} = \int_{z_i}^{z_i + \frac{\Delta z}{2}} B(z') dz' = -\frac{1}{2} e^{-2\tau(z)} \Big|_{z_i}^{z_i + \frac{\Delta z}{2}} = \frac{1}{2} \left(e^{-2\tau\left(z_i + \frac{\Delta z}{2}\right)} - e^{-2\tau(z_i)} \right). \tag{A9}$$

If we note that $\tau(z_i + \frac{\Delta z}{2}) - \tau(z_i) = \frac{\alpha_i \Delta z}{2}$ and $\tau(z_i) - \tau(z_i - \frac{\Delta z}{2}) = -\frac{\alpha_i \Delta z}{2}$, then Eqs. (A7)–(A9) lead to the following:

$$B_{i,1} = B_i \left(\frac{e^{\alpha_i \Delta z} - 1}{e^{\alpha_i \Delta z} - e^{-\alpha_i \Delta z}} \right), \tag{A10}$$

and the following:

$$B_{i,2} = B_i \left(1 - \frac{e^{-\alpha_i \Delta z}}{e^{\alpha_i \Delta z} - e^{-\alpha_i \Delta z}} \right). \tag{A11}$$

Using Eqs. (A10) and (A11), we can now determine the correction terms $IRES_1$ and $IRES_2$ that are applied as multiplicative corrections to the leading and tailing terms, respectively, in the summation representing the integration term in Eq. (11) as follows:

$$IRES_1 = 2 \frac{e^{\alpha(z) \Delta z} - 1}{e^{\alpha(z) \Delta z} - e^{-\alpha(z) \Delta z}}, \tag{A12}$$

and as follows:

$$IRES_2 = 2 \frac{1 - e^{-\alpha(z) \Delta z}}{e^{\alpha(z) \Delta z} - e^{-\alpha(z) \Delta z}}. \tag{A13}$$

Note that in the optically thin limit, where $\alpha \Delta z$ tends to zero, $IRES_1$ and $IRES_2$ both tend, as expected, to 1. When $\alpha \Delta z$ is very large, however, then $IRES_1$ tends towards a limit of 2, and $IRES_2$ tends to 0.

A2 Resolution correction for remaining terms

We now turn our attention to the impact of finite range resolution on the terms not associated with the integral term in Eq. (11). The boundary value of the extinction (e.g. α_0) is obviously not impacted; however, the other terms will be affected. In particular, since we are seeking the retrieved extinction values valid at the mid bin point, we must establish the relationship between the bin accumulated signal and the associated mid bin values.

We start by noting that, in terms of $B(z)$ and τ , the single scattering lidar equation (see Eq. A6) can be rewritten as follows:

$$B(z) = \alpha(z) \exp(-2\tau(z)), \tag{A14}$$

and the bin mid value ($B_{m,i}$) of the i th bin is then just the following:

$$B_{Mid,i} = \alpha(z_i) \exp(-2\tau(z_i)). \tag{A15}$$

Equations (A7) and (A15) can then be combined to show that, in the following:

$$\frac{B_{m,i}}{B_i} = \frac{2\alpha_i}{e^{\alpha(z) \Delta z} - e^{-\alpha(z) \Delta z}}. \tag{A16}$$

Thus, the desired general form of the correction term (RES_2) to be applied to the P' terms in the numerator of Eq. (11) and the first term of the denominator (but not to the terms under the integral) is as follows:

$$RES_2(z_i) = \frac{2\alpha_i \Delta z}{e^{\alpha_i \Delta z} - e^{-\alpha_i \Delta z}}. \tag{A17}$$

We note that the term, as expected, tends to 1 for small values of $\alpha_i \Delta z$.

Code and data availability. The algorithm and data used in this publication were published through Zenodo and are available at <https://doi.org/10.5281/zenodo.5090535> (Sarna, 2021).

Author contributions. KS developed the software code described in this paper and wrote the paper. DPD contributed to the mathematical derivation of the problem and contributed significantly to the original draft, did the proofreading, and provided guidance throughout the development process. HWJR evaluated and proofread the paper and provided guidance as the supervisor of KS.

Competing interests. The authors declare that they have no conflict of interest.
